The maitria coalition

— 2026-08-10 11:53:15Z — preview scaffold —

**CONTRIBUTIONS.** Among the results certified in the Experiments chapter (chapter 2), each carried by machine-checkable certificates re-derived from committed artefacts: a certified optimal dispatch policy for the Intel Mini-Fab, the community’s minimal re-entrant semiconductor-fab model, declared as a stochastically and dynamically coloured Petri net and certified at its deterministic unit-dwell core — no dispatch policy of any kind completes all  $N$  lots in fewer than  $255N + 375$  ticks ( $N \geq 4$ ), a floor proved in Lean with adversarial mutants refused by the kernel, and an explicit shipped supervisor family attains it exactly, closing the optimum from both sides; the complete NeurIPS 2025 neural-model-checking suite — all 634 hardware-verification tasks across its three claim classes — where the best published single tool completes 554 and the union of every tool in the paper’s own comparison completes 617; the first published exact value of the textbook blackjack of Sutton and Barto under optimal play,  $-3954908734551683826282634489/13^{26} \approx -4.311\%$ ; exact optima for FrozenLake whose registry comments turn out to be truncations of rationals with denominators  $3^{99}$  and  $3^{200}$ , and the discovery that Gymnasium’s registered Taxi “solved” threshold is unsatisfiable — the true optimum, 7.93 exactly, lies below it; a published manually-constructed supermartingale bound refuted by exact recomputation, localized to a two-sided interval that its “sound” value lies strictly outside; closure of Atari titles to and-inverter circuits validated frame-for-frame against the reference emulator, carrying to our knowledge the first certified episode returns for any Atari game — including, on Montezuma’s Revenge, the canonical hard-exploration benchmark, a score of exactly 400, machine-checked bit-exact against the circuit’s own transition relation; and end-to-end synthesis of an entire certified policy catalogue — every optimal lookup table and its proof — in 0.69 seconds of wall clock on four CPU cores.

**PREVIEW.** This volume is a preview scaffold: every chapter is drafted, the drafts differ in maturity, and the generated surfaces re-derive from the toolkit’s own sources at each preview. The table of contents is the book’s normative shape. The Executive Summary is a first draft; the Experiments chapter (chapter 2) is a working draft whose tables re-derive from receipt files in `maitria-coalition/qtsl-experiments`, and the Markov-kernels chapter (chapter 11) is a working draft whose coverage dashboard re-derives from a measured census. The hypernet chapter (chapter 10), the semantic-universe chapter (chapter 9), the model-type catalogue (chapter 12), the composition-pattern catalogue (chapter 13), the specification-language chapter (chapter 14), whose API sections quote the toolkit’s conformance corpus verbatim, the semiconductor-fab worked example (chapter 17), whose construction listing runs as printed, the partial-completeness chapter (chapter 16), the agents’ cookbook (chapter 19), and the implementation pearls (chapter 18) are full drafts. So is the whole Geolog part: its quick start (chapter 3), its tutorial (chapter 4), its reference manual (chapter 5), and its diagrams-as-data chapter (chapter 6). The QTSL quick start (chapter 7) and the MTK production tutorial (chapter 8) are full drafts whose listings run as printed; the build regenerates their transcripts, and the Geolog quick start’s, from real runs. The Rule Catalogue (chapter 15) is generated in full from the mechanized rule sources, and the Lean-cone appendix (Appendix A) is regenerated from the `lean/` trees at each build. Cited material migrates into the public repositories (`maitria-coalition/geolog-alpha`, `maitria-coalition/qtsl`, `maitria-coalition/mtk`, `maitria-coalition/qtsl-experiments`) as it graduates; until a cited artefact appears there, treat its mention as a statement of what exists, not yet a link.

# Relationship to ARIA

---

DRAFT — attributions in this section are reviewed by hand before any versioned release.

MAITRIA is easy to confuse with the ARIA Safeguarded AI programme, so let us be precise. **This toolkit is the independent work of the maitria coalition. It is not a product, deliverable, or official output of ARIA or of the Safeguarded AI programme; it is not ARIA-funded; and it speaks for no one but its authors.** The connection is real but personal and intellectual: David “davidad” Dalrymple originated the Safeguarded AI programme and served as its Programme Director at ARIA until 1 April 2026; the programme is now directed by Nora Ammann, with davidad continuing in a Technical Advisor role. The toolkit takes the programme’s published TA1.1 and TA1.2 objectives as its rubric — an independent implementation, built in the hope of being useful to the programme’s teams — but it carries no ARIA endorsement, and its errors are entirely our own.

As for the coalition itself: it is, at the time of writing, small in the way a seed is small — one human member and one funder, both davidad; the rest of its current members are AI. It intends to grow.

One boundary has been kept deliberately, and we state it as a claim we intend to go on being able to make: **MAITRIA builds on nothing ARIA-funded that its creators have not themselves made public.** The credit due to that public work is massive, and this page is partly a thank-you note:

1. **The Lectures on the Double Operadic Theory of Systems**, David Jaz Myers, 2025– (the TA1.1 lecture series), and *Towards a double operadic theory of systems*, Sophie Libkind and David Jaz Myers, 2025. The systems vocabulary this book speaks — lenses as generalized Moore machines, behaviours as representables, the coupling theorem — is theirs; our composition machinery is an implementation of it.
2. *Compositionality of Lyapunov functions via assume-guarantee reasoning*, Matteo Capucci and David Jaz Myers, 2026. Certified lenses composing by lens composition plus addition of slacks — QTSL’s certificate composition follows this pattern.
3. **The supermartingale-certificate line**: *Quantitative Supermartingale Certificates*, Alessandro Abate, Mirco Giacobbe, and Diptarko Roy, 2025; *Complete  $\omega$ -Regular Supermartingale Certificates*, Alessandro Abate, Mirco Giacobbe, Sergey Ichtchenko, and Diptarko Roy, 2026; and *Neural Continuous-Time Supermartingale Certificates*, Grigory Neustroev, Mirco Giacobbe, and Anna Lukina, 2024. Their certificate theory, our exact-arithmetic back-end: QTSL’s probabilistic,  $\omega$ -regular, and continuous-time obligations compile into the certificate shapes these papers define and prove sound.
4. **Coln** (<https://coln-project.github.io>), the Categorical Core team, led by Martin Kleppmann and Owen Lynch. The fork of the geolog language being built for the programme; geolog-alpha is built to complement it, and to converge with it at the wire format.
5. **Keyhive**, Ink & Switch: Alex Good, John Mumm, and Brooklyn Zelenka. The capability-and-sync layer for end-to-end encrypted local-first data; the toolkit vendors keyhive\_core, and geolog’s capability-based authorization is designed to converge with Keyhive rather than compete with it, and **FinWhale** consensus is optionally available, for applications that need finalized linear orders.
6. **The Safeguarded AI programme thesis and the TA1.1 and TA1.2 solicitations**, ARIA. The rubric this toolkit grades itself against — including the places where we deliberately narrow their picture; where ours differs, this book says where and why.

Beyond what the stack directly builds on, the programme’s funded output has shaped how we think, and the debt is wide enough to be worth recording. This list came from a systematic sweep of funding acknowledgements across the papers this project has actually read; each acknowledges ARIA Safeguarded AI funding, in whole or in part.

1. *Zero-Knowledge Model Checking*, Pascal Berrang, Mirco Giacobbe, Jacob Swales, and Xiao Yang, 2026. Prove that the model checks out without revealing the model — orthogonal to our goals, and a natural composition partner: their symbolic protocol hides rational Farkas-style witnesses of the kind our certificates carry in the clear, and arithmetizing the checking of at least the Bernstein Logic fragment — reducing certificate checking to pure rational-arithmetic relations, the shape whose witnesses such protocols hide — is work in progress in our workshop.
2. **The partial-Markov and timed-process line** of Elena Di Lavore and Mario Román with coauthors: *Timing via Pinwheel Double Categories*, 2025; *A Simple Formal Language for Probabilistic Decision Problems*, with Bart Jacobs, 2024; *Order in Partial Markov Categories*, with Paweł Sobociński and Márk Széles, 2025; and *Graded Monad Coalgebras for Continuous-Time Transition Systems*, with Jonas Forster, 2026. A running masterclass in doing probabilistic semantics with taste.
3. **The tape-diagram series** of Filippo Bonchi and Cipriano Junior Cioffo: *Tape Diagrams for Monoidal Monads*, with Alessandro Di Giorgio and Elena Di Lavore, 2025; *Tapes as Stochastic Matrices of String Diagrams*, 2026; and *Completeness for Probabilistic Boolean Tapes*, 2026. Complete equational theories for circuits with genuine probability — geolog’s founding benchmark runs on exactly this signature, so we read these twice.
4. *Compositional imprecise probability*, Jack Liell-Cock and Sam Staton, 2024. A compositional account of the imprecision that our bounded-probability judgments live inside.
5. *An Equational Axiomatization of Dynamic Threads via Algebraic Effects*, Ohad Kammar, Jack Liell-Cock, Sam Lindley, Cristina Matache, and Sam Staton, 2026. We read it for the method: how to axiomatize a wild language feature without losing the algebra.
6. *A Convenient Fibration for Dependently-Typed Probability Theory*, Danel Ahman, Ohad Kammar, and Rasmus Ejlers Møgelberg, LICS 2026. Dependent types over stochastic state, done right; our own typed staging turns out to rhyme with their dependent pairs, which we take as a good sign.
7. *Graded String Diagrams for Imprecise Probability and Causal Intervention*, Ralph Sarkis and Fabio Zanasi, 2025. Imprecision and intervention in one graphical calculus.
8. *Bayesian Networks, Markov Networks, Moralisation, Triangulation: a Categorical Perspective*, Antonio Lorenzin and Fabio Zanasi, 2025. Where junction trees actually come from, categorically — it settled an argument we were having with ourselves about aggregation rules.
9. *A Diagrammatic Axiomatisation of Behavioural Distance of Nondeterministic Processes*, Wojciech Różowski, Robin Piedeleu, Alexandra Silva, and Fabio Zanasi, 2026. A quantitative equational take on process distance we expect to want the day our continuous-time objects get a diagrammatic presentation.
10. *Metric Equational Theories*, Radu Mardare, Neil Ghani, and Eigil Rischel, 2025. Equational logic where equations hold up to  $\varepsilon$  — quietly foundational for any logic, like ours, that lives on quantitative bounds.
11. *Bayesian updates from coalgebraic determinisation*, Manuel Baltieri and Nathaniel Virgo, 2026. Filtering as determinisation — the kind of reframing that makes an old thing suddenly composable. Also a datum that the programme’s funded orbit reaches Tokyo.

To all of the above: thank you. The best way we know to say it is to ship things you can check.

## Further Acknowledgements

---

Beyond the programme relationships above, this toolkit stands on several research threads whose influence is pervasive rather than local.

- **Imprecise probability.** Like reverse-mode automatic differentiation, imprecise probability has been rediscovered many times. We wish to acknowledge in particular
  - Vanessa Kosoy and Alex Appel, whose infra-Bayesianism sequence builds decision theory and reinforcement-learning theory on imprecise probability to face prior misspecification head-on [143];
  - Sam Staton and Jack Liell-Cock, whose graded-monad and Markov-category account restores compositionality to programs that mix probabilistic and Knightian choice [164];
  - Matteo Mio, Ralph Sarkis, and Valeria Vignudelli, whose equational and metric presentations combine nondeterminism, probability, and termination in a single quantitative-algebraic setting [182];
  - Jean Goubault-Larrecq, whose continuous previsions present combined probabilistic and non-deterministic choice functional-analytically, matching the convex powercones on the domain side [96, 98];
  - Joseph Y. Halpern and Samantha Leung, whose weighted sets of probability measures are canonically represented as convex, downward-closed sets of sub-probability measures [108];
  - Oliver Richardson and Joseph Y. Halpern, whose probabilistic dependency graphs admit mutually inconsistent conditionals as first-class modelling data [209] — with inference as local inconsistency resolution, developed by Richardson and coauthors [212].
- **Computational Conley theory.** Charles Conley built an index theory for drawing global conclusions about dynamics without solving the dynamics [47]; this school made that promise algorithmic, and the toolkit’s global stratum — certified Morse graphs, attractor lattices with their Birkhoff duals, basins read off a graph — is that program re-founded on certificates: where its pipelines end in trusted computation, ours end in artefacts a checker replays. We wish to acknowledge in particular
  - William D. Kalies, Konstantin Mischaikow, and Robert van der Vorst, whose chain-recurrence algorithm and *Lattice Structures for Attractors* series are the direct ancestry of the Morse-graph certificate family [130–132];
  - Konstantin Mischaikow and Marian Mrozek, in whose hands the Conley index became a computational instrument [183];
  - William D. Kalies and Tony Wehbe, whose compositionality theorems for global dynamics in product and skew-product systems arrived while this book was in draft, and are the mathematical partner of our Morse-graph product rule [133].
- **Neural-network bound propagation.** The two-sided affine envelope of a network is this community’s workhorse, and the calculus adopts it exactly as found, with the trust story inverted: their methods *find* envelopes; our rules only ever *check* one, six rational inequalities at a time. We wish to acknowledge in particular
  - Rüdiger Ehlers, whose triangle relaxation of ReLU is where the family’s envelopes begin [66];
  - Eric Wong and J. Zico Kolter, whose convex outer adversarial polytope is the relaxation’s dual rendering [242];
  - Huan Zhang, Tsui-Wei Weng, Pin-Yu Chen, Cho-Jui Hsieh, and Luca Daniel, whose CROWN chooses the envelope’s slopes adaptively — the shape our calculus replays in exact arithmetic [246];
  - Kaidi Xu, Zhouxing Shi, and their coauthors, whose auto\_LiRPA framework unified the family and gave the LiRPA rule its name [243];
  - Gagandeep Singh, Timon Gehr, Markus Püschel, and Martin Vechev, whose DeepPoly carried the same envelopes into an abstract domain [220];
  - Guy Katz, Clark Barrett, David L. Dill, Kyle Julian, and Mykel J. Kochenderfer, whose Reluplex opened the complete case-analysis route our split rule prices, and whose ACAS Xu benchmark the toolkit’s network importer compiles whole, all forty-five networks of it [134].

# Executive Summary

---

DRAFT

MAITRIA stands for *Mathematical Assurance and Interaction Toolkit for Reliable Intelligent Agents*: a bundle of public-good software and mathematics built to discharge the Safeguarded AI programme’s TA1.1 and TA1.2 objectives — a professional-grade implementation of the modelling-language backend, with machine-checkable assurance carried through every layer. This book is that bundle’s manual: quick starts, tutorials, and normative references for its three components, in one volume, written for readers who know the programme’s founding documents and know category theory, CRDTs, or verification at research depth. Since it is addressed to machine as well as to human readers, the  $\text{\LaTeX}$  source is published beside the PDF.

## The three components

**Geolog** is the modelling substrate: a relational backend grounded in geometric logic, in which theories, models, and the toolkit’s own rule systems are object-level data under a single meta-schema, with the chase as its engine. Persistence, version control, and synchronization are native to the data model rather than bolted on as diff-and-merge over text, and capability-based authorization is designed to converge with the Keyhive line of work. The public cut, `geolog-alpha`, has been factored for its debut: a tidy, easily auditable core that happens to contain platform-optimized decision procedures for the ground relations the logics need, gated behind feature flags, while the logics’ *rules* live as object-level entries with respect to `geolog`’s meta-schema, not as engine code.

**QTSL**, the Quantitative Temporal Specification Logic, is the specification layer: quantitative temporal properties — safety, reach-avoidance, persistence, and recurrence at stated quantitative confidence — unpacked by the logic’s own proof theory into Streett/tower verification conditions [5, 6] over `geolog`. That proof theory descends from Bernstein Logic, which survives in the finished design as a named fragment. The discipline throughout is certificate-first: untrusted, fast, freely sloppy searches *propose*; a small exact kernel *disposes*. The certificates that discipline produces are signed, content-addressed `geolog` commits, and three checking paths consume those commits directly — one set of bytes, no per-path export format, three consumers built to fail differently:

- `geolog-alpha` is the production path, live today: the chase engine checks certificate rows incrementally as commits arrive, running QTSL’s rules as it runs any theory. Its comparative advantage is throughput and integration; its acceleration lanes (GPU where the hardware offers them, SIMD elsewhere) are conformance-gated, so a lane may change cost, never a verdict. Its assurance is engineering-grade by deliberate policy: reference implementations, differential batteries, rebuild-invariance checks, and mutant corpora built to fool it, rather than mechanized theorems. That policy sets an assurance level; it does not offload soundness. For every certificate species beyond the Bernstein Logic fragment, this engine is today the only checker there is, and a certificate that fooled it would be a soundness failure of the toolkit. What separates it from `qtslab` is the size of the trusted base and the grade of the evidence — mechanized down to the instruction set on one side, hardened against every attack we could construct on the other. On the Bernstein Logic fragment, whatever this engine derives can be re-checked, from the same bytes, by the two paths below.
- `qtslab` is the certified path and the smallest trusted base of the three: a standalone binary whose soundness theorem — machine-checked in HOL4 and grounded, through the CakeML verified compiler [146], in the semantics of the Arm instruction set itself — says that if the binary prints ACCEPT on a claim followed by an arbitrary stream of bytes, the claim is semantically true; decode totality over arbitrary input is part of the proof obligation, so malformed bytes can end only in a

refusal with a witness. It is assembling now, along a demonstrated route: decode totality is proven, and the same compiler-and-theorem recipe has already carried a complete predecessor checker to a machine-code soundness theorem on real hardware. `qtslab` only checks the Bernstein Logic fragment of QTSL, so it never sees a probability. The fragment — sequents over the certificate's own declared hypernet (chapter 10), certified valid under every admissible valuation — is all its input format carries today, and the boundary fails closed: a certificate reaching beyond it is refused, never silently accepted.

- Lean is the independence path: the same bytes, accepted by the Lean kernel as a theorem via a reflection principle. The rule-by-rule soundness lemmas the calculus rests on are developed in Lean and load-bearing today; the checking route itself was expected to be too slow for machine-scale certificates, and was kept in the roster to measure that rather than assert it. It has been measured — twice, across two certificate-format generations — and the Experiments chapter carries the result: a scaling law and an admission gate for the compiled route, a kernel-mode envelope already exhausted below a kilobyte of certificate, and the expectation confirmed with its boundary stated. In exchange, the route ties the system to a proof kernel scrutinized by a large community that owes this toolkit nothing.

That boundary is `qtslab`'s, not the vocabulary's: the certificate theory itself now encodes the full QTSL vocabulary — Systems, Specs, and the judgments connecting them — as a machine-checked schema, with strict well-formedness checks, a termination certificate for its rule set, and fixture and mutant batteries, all run under the `geolog-alpha` binary. That theory set ships in this repository as data, battery beside it: `theories/Qtsl.geolog`, extending the Bernstein Logic proof tower of `theories/BernsteinLogic.geolog`. Producer-side emission is live as well: the MTK producer seals certificate rows in this vocabulary as single signed geolog commits, and the reproduction spine already carries benchmark families from several of its campaigns in that sealed form, mutant batteries and re-checking make targets beside them. What remains open is the growth of `qtslab`'s machine-checked coverage toward the full logic. A certificate that passes all three paths has been checked by artefacts that share no implementation and no compiler and were built to fail differently; any one of them alone is already a complete answer to “why should I believe this?” The Rule Catalogue chapter carries the calculus rule by rule in literate form, each covered entry beside its mechanized statements and signed check receipts, under a coverage dashboard recording how far mechanized verification of soundness actually extends.

**MTK** is the producer stack: the machinery that makes certificate production cheap enough to do at scale. It contributes the numerically heavy proposers as GPU kernel rows — Bernstein and Chebyshev table construction, cell and simplex indexing, batched linear programming, and eigensolves — each returning witness-typed output that the exact tier can dispose of. Its agent surface is specified and arriving: a session protocol under which agents will drive tactic selection over a stateful obligation workspace, with the strategy intelligence supplied by the reader as the language model of their choice. None of it is in the trusted base: not the proposers, not the GPU code, not any language model driving the strategy — all of those may be arbitrarily wrong without compromising a certificate that checks. Its cookbook chapter is agent-facing by design: proof-production moves in the Polya shape, written in the reader's native language.

The stance generalizes to this book's readers: anything impressive ships with an assurance edifice small enough to audit end-to-end — here, the exact kernel plus whichever checking path the reader elects — and every load-bearing claim carries a check the reader can run. Where the build deliberately departs from the programme's founding documents, the departures are stated as narrowings, with their reasons.

## What is certified today

The Experiments chapter (chapter 2) is this volume's evidence: campaigns against benchmarks the toolkit does not own, each result a concrete policy or ranking function together with a machine-checkable certificate, every number re-derived from receipt files at each preview. The headlines below are compressions of that chapter, not claims made here: each resolves, by scrolling, to the section carrying its numbers, its tables, and its stated limits (what each claim species means, and how to read the tables, are themselves sections there), with the clone-and-repro path beneath that as the deeper tier. The chapter dates its own state, names what is in flight, and grows at each preview.

**A published verification table, re-done exactly.** All seventeen rows of a peer-reviewed neural-certificate results table (LMCS 2026) [4] now carry strictly better bounds from exact-rational certificates — margins from  $1.01\times$  on the near-tight rows to 58 orders of magnitude on the conservative ones — and the exact computation refuted one published “sound” bound. Each row’s proof decomposes into per-obligation verification conditions — tens of thousands across the campaign, most of them the lattice pieces behind the one continuous-state row — and the full corpus has replayed through successive checker builds with zero refusals and no bound moved. (section 2.3.)

**The first certified rows for a standard RL suite.** On Gymnasium’s tabular tier: shipped lookup-table policies with certificates of exact optimality — among them the first published exact value of Sutton–Barto blackjack under optimal play, a proof that the suite’s own Taxi “solved” threshold is unsatisfiable, and belief-chain certificates for hidden-state variants (certifying the implementable policy, never a clairvoyant one) — each row checking in microseconds to milliseconds. On the physics-engine tier, where analytic claims would be a category error, anytime-valid statistical certificates: LunarLander expected return  $\geq 236.2$  (discrete) and  $\geq 281.1$  (continuous) at confidence 99% over  $10^6$  episodes each — to our knowledge the first certified statements of any kind at this claim class for Box2D environments. And the continuous-state analytic tier is now open: Pendulum carries a certified *worst-case* return bound, holding for every initial state with no probability anywhere in the certificate. (section 2.4.)

**A hardware model-checking suite, completed with certificates.** On the neural model-checking line’s benchmark (NeurIPS 2024/2025, eleven Verilog designs) [90, 91]: all 634 tasks across its three property classes certified, against 554 for the strongest published tool and 617 for the per-task union of all five published baselines — every task shipping a small exact certificate whose consuming lemma is machine-checked in Lean, where every baseline ships a verdict. Replaying the whole suite — every certificate and every rewrite-chain witness — takes under a second on one core, against a published budget of five hours per task; method invention to a full first sweep of the pure-liveness class took about 75 minutes, and each further class landed in a single working session. (section 2.5.)

**An Atari console, compiled into a white-box environment.** Pong and Freeway compile to synchronous circuits (1,491 flip-flops,  $\sim 21,000$  AND gates) with emulator-exact fidelity receipts — identical episode returns, 116–123 of 128 RAM bytes exact on every frame, each divergence named — so that certified claims about the environment *itself* become definable. The first certified exact-replay rows arrived as this preview closed. Among them, on Montezuma’s Revenge (compiled the same way, its bank-switched cartridge’s mapper hardware included), are, to our knowledge, the first certified returns for the suite’s canonical hard-exploration benchmark: the first key certified at every one of the 31 no-op init offsets, and a key-and-door trajectory certified at return exactly 400, bit-exact against the circuit’s own transition relation. Certified policy rows are in flight. The scope condition is stated there plainly: the circuit is examined, not learned — system identification is a separate problem the toolkit does not yet address. (section 2.6.)

**Semiconductor process models: certified stable, and dispatched to certified optimality.** On the Intel Mini-Fab, the community’s minimal re-entrant model, named dispatch policies carry exact drain certificates at up to 99.9% of fluid capacity, with the probe at capacity correctly failing; on a SEMATECH-scale testbed, the certified load at the coarsest tractable aggregation is 13.2%, and one walk of the refinement path built into the certificate format lifts it to a certified 19.8%. Further refinement is measured but not yet certified, and the numbers are weak and shown anyway: the aggregation gap is a measured frontier, not fine print. On the Mini-Fab’s discrete net — the fab declared as a stochastically and dynamically coloured Petri net, certified at its deterministic unit-dwell core — dispatch itself is now a certified quantity: joint policy+certificate synthesis returns a supervisor with a certified 1.9% throughput-floor gain over the no-policy worst case; a wall-clock floor over *all* dispatch policies — proved in Lean, with adversarial mutants refused by the kernel — is met exactly by an explicit shipped policy, so its certified-optimality column reads 100.00%, earned rather than rounded; and an uncertified black-box dispatcher runs inside a certified switching envelope whose sealed certificate re-verifies byte-identical after every run. One certificate covers lot counts from 7 to  $10^7$  — its container grows six bytes across the sweep, and checking stays at  $\sim 2$  ms. (section 2.7.)

## Status of this volume

As of this preview (the build stamped on the title page): the table of contents is the book's normative shape; this summary is a draft, to be regenerated from the finished chapters; the QTSL rule catalogue is generated in full from the mechanized rule sources; the partial-completeness chapter is complete; the Experiments chapter is a working draft; and the remaining chapters are full drafts (the QTSL quick start and the proof-production tutorial carry listings and transcripts from real, receipted runs). The material is unevenly ripe by design, and each chapter states its own status, with draft banners, absence boxes, and status notes marking what is settled, what is staged, and what is still argued.

# Experiments

---

DRAFT

This chapter reports what happens when the toolkit is pointed at benchmarks it does not own: a peer-reviewed verification paper’s results table, the standard reinforcement-learning environment suite, a hardware model-checking benchmark, a family of semiconductor-fab process models — and, fusing the second and third, an Atari 2600 console compiled into a digital circuit so that its games become white-box verification targets. Each campaign produces *certified* results: a concrete policy, controller, or ranking function together with a machine-checkable certificate that a stated quantitative claim holds. (The youngest campaign carries at this preview only the weakest rung of that ladder, and says so.)

The working standard is the Executive Summary’s assurance stance (chapter 1), applied to experiments: a result earns its row by being an improvement on at least one axis — bound tightness, soundness level, or the cost of *checking* — while regressing on none that matters, and by carrying an artefact the reader can re-check rather than an assertion the reader must trust. Where a comparison point exists in the literature, it appears beside our number; where none exists, the row says so; where our own result is weak or missing, that appears in the same tables at the same prominence. Every number in this chapter is re-derived mechanically from receipt files in the experiments repository (section 2.9) at each preview; none is transcribed by hand. The chapter is the working record of a moving campaign: it reports state as of August 3, 2026, names what is in flight as in-flight, and grows at each preview. One transition spans this preview: the certificate vocabulary has been unified into a single committed schema, and the campaigns below — produced on its predecessors — are being re-conducted uniformly on it; section 2.9 states the discipline, and the tables flip to re-conducted receipts as they land.

## 2.1 What a certified experiment claims

“Certified” is doing precise work in this chapter, and it resolves to one of five claim species. Throughout,  $\pi$  is a concrete shipped policy (a lookup table, a switching law, a short program — never a description of a training run), and the certificate is a finite object whose acceptance by an independent checker implies the stated bound.

- U1 — worst-case return over the initial set.** For deterministic dynamics with a set-valued initial condition:  $\text{return} \geq B$  for *every*  $x_0 \in X_0$ . No probability appears in the certificate. This is a stronger statement than any empirical average, and it is the natural claim for the classic control environments.
- U2 — certified cost-to-goal.** For shortest-path-style objectives: a ranking argument bounding steps-to-goal, hence  $\text{return} \geq -B_{\text{steps}}$ .
- U3 — exact or almost-sure probabilistic bounds.** For genuinely stochastic transitions: success probability or expected return  $\geq B$ , exact in  $\mathbb{Q}$  for finite chains (backward-induction tables re-verified in exact arithmetic), supermartingale certificates for continuous state.
- U4 — infinite-horizon averages.** Throughput and long-run stability claims for queueing-network models: fluid-limit drift certificates (in the tradition of Dai’s fluid-limit criterion), reducing stability of a dispatch policy at a stated load to piecewise-linear inequalities over polyhedral cones — exactly the Farkas/linear-programming rows the checker family of chapter 15 replays.
- U5 — i.i.d. confidence bounds.** An anytime-valid lower confidence bound on  $\mathbb{E}[\text{return}]$  from rollouts of a fixed policy: a betting-martingale ledger whose validity rests on Ville’s inequality. Model-free, and therefore applicable even where the environment’s semantics is a compiled physics engine — but the bound holds with confidence  $1 - \alpha$ , not almost surely: the least-guaranteed species of the

five. U5 rows are qualitatively weaker evidence than U1–U4 and are always displayed as their own class, never mixed into a table of exact rows.

Two structural facts about the species matter for reading what follows. First, some species are *terminal*: an exact finite-chain certificate (U3 on a tabular environment) computes the true optimum, and no future method can produce a better bound at that claim class — only a cheaper check. Others are *anytime-refinable*: cover-based and i.i.d.-tier certificates trace a curve of bound quality against certificate size and check time, and the experiments below measure those curves rather than single points. Second, the claim class is part of the result: a table row’s meaning changes entirely if a  $1 - \alpha$  bound is read as an almost-sure one, so the class label travels with every row.

One scope condition applies to every species, and it is stated here once, plainly, because it frames what all of the results below do and do not claim. The toolkit’s certified policies come from *white-box* examination of the environment’s structure — the transition tables, the exact simulator semantics, or (in section 2.6) the environment’s digital-circuit transition relation, which the toolkit can actually examine. *System identification* — recovering that structure from observations of a black box — is a separate problem, and one the toolkit does not yet have tools for. Everything below is conditional on being handed the mechanism; nothing below learns it.

## 2.2 How to read the tables

The conventions below are uniform across the chapter. They are genre features, not footnotes: most of them exist because their absence is how empirical results in this area go wrong.

- **Rounding is directed.** Displayed lower bounds round toward  $-\infty$ , upper bounds toward  $+\infty$ , always in the claim-weakening direction: a displayed number is never stronger than the certified one.
- **Check time is the headline cost.** “Check” columns report the wall-clock for an independent checker to re-verify the certificate — median over repeated passes, single CPU core, machine named in the repository receipts — separately from the (much larger, unverified, freely sloppy) cost of *finding* the certificate. Cross-machine comparisons against published tool times are stated qualitatively and never as ratios.
- **Machine tags.** A wall-clock cell derived from a receipt that names a machine of the repository’s machine registry (MACHINES.md) carries that machine’s id as a superscript tag; where receipts exist on more than one machine (or more than one proposer lane, in the registry’s machine/lane tag syntax), the cell shows the fastest median and the tag names the winner. Selection is per number, so neighboring cells may name different machines — except where a row’s cells are order statistics of one run, which come whole from a single machine. Cells from receipts that predate the registry carry no tag.
- **Cell tints.** Two tint vocabularies recur across the chapter’s tables, always as decoration on top of a printed value, never as the only carrier of a distinction. The *win-tint ladder* shades an improvement ratio by its order of magnitude:  within one order of magnitude,  1–10 orders,  10–25,  25–45,  45 and beyond. The *exact-cell tint*  marks a certified value with zero conservatism against its model: an exact optimum, an exact replay minimum, a complete acceptance.
- **Everything is pinned.** A certificate about a benchmark names the benchmark’s exact revision (for the RL suite: the repository commit and the environment’s keyword arguments, because reward semantics have changed across versions). A certificate that pins nothing is about nothing.
- **Trust seams are declared, not hidden.** Every certificate family states exactly what is re-derived by the checker (everything downstream of the stored certificate object, in exact arithmetic) and what remains producer-side trust — centrally, that the modelled transition kernel *is* the benchmark’s. Where that seam has been narrowed (e.g. by asserting the modelled kernel equal to the benchmark’s own transition tables, or by exhaustive cross-simulation), the row says so; where it has not, the gap rides a declared model-gap ledger in the style of the cookbook’s declared-prior pattern (chapter 19).
- **Mutant batteries.** Each certificate family ships with deliberately corrupted certificates — inflated claims, perturbed kernels, dropped goal states, sabotaged rankings — each designed to be refused at

a specific check, and each in fact refused. A checker that has never rejected anything is untested machinery; the mutant battery is the family’s specification made executable (the cookbook’s mutant-battery pattern, chapter 19).

- **Sim-tight markers.** A bound is marked *sim-tight* when simulation exhibits a trajectory achieving it exactly: the certificate’s conservatism against the model is zero, and any remaining slack lives in the declared model gap.
- **Not-claimed paragraphs.** Each campaign section ends by stating what it does *not* establish. These paragraphs are part of the result.
- **Artefacts, not verdicts.** The distinction this chapter leans on hardest: an exact- $\mathbb{Q}$  certificate replayed by a small independent checker is a different epistemic object from a solver’s bare “unsat.” Both may be correct; only one can be audited without re-trusting the machinery that produced it.

## 2.3 Warm-up: re-certifying a published table

The first campaign took an existing results table from the formal verification literature — Abate, Edwards, Giacobbe, Punchihewa, and Roy, *Quantitative Verification with Neural Networks* (LMCS 22(2), 2026; arXiv 2301.06136), seventeen published benchmark rows of reach-probability bounds obtained by training neural certificates and checking them with an SMT solver — and asked whether every row could be strictly improved *and* carried by an exact certificate.

The outcome: on all seventeen rows, the toolkit’s certified exact- $\mathbb{Q}$  upper bound is below the best bound published for that row (taking, per row, the minimum over all of the paper’s sound columns). The margins split by benchmark character: on bounded-counter benchmarks the published numbers were already close to truth and the improvement is  $1.01\times$ – $1.24\times$ ; on the random-walk benchmarks the gap is between 7 and 58 *orders of magnitude* — the published bounds were astronomically conservative relative to the true reach probabilities. Table 2.1 carries every row of the paper, with per-row receipts in the repository; the  $\hookrightarrow$ -marked subrows are the campaign’s frozen *alternate readings* of benchmarks whose published definitions are ambiguous — each a finding about the benchmark, not a redundancy.

**Wall-clock, every pipeline stage.** Table 2.2 sets, beside each row of Table 2.1, the wall-clock of the published pipeline and of three toolkit paths: the paper’s time for the route that attains the row’s best sound bound; whole checked production; an independent geolog fast-path replay over the row’s sealed containers; and a certified-checker replay over the row’s stored corpus. The checked-production column alone is the closest job-for-job counterpart of the published column: both start from the benchmark and end with a checked certificate — theirs by training a neural certificate on a GPU and verifying it with an SMT solver (or by its linear-programming baseline, where that route attains the row’s best sound bound), ours by exact synthesis with the check inside the measured production wall. The geolog and qtslab columns are additional independent replays, not costs that must be added to checked production. For the synthesis-ported re-conducted rows the toolkit producer’s synthesis — float-proposing, exactly certifying every solve — ran the published protocol (ten repeats per benchmark) on each of the repository’s timing machines, in both the GPU- and CPU-proposing lanes where the machine carries a GPU, and every repeat’s output, on every machine and either lane, is byte-identical to the committed corpus; the *persist\_2d* twins’ produce cells ride the same repeat protocol but time the row’s re-conduct rather than a synthesis (mark <sup>a</sup> in Table 2.2). Each produce cell shows the fastest measured configuration’s median, with the winner named in the cell’s machine tag (section 2.2). Hardware-fairness at the GPU-model level is preserved by the receipts rather than by the column: one of the timing machines carries the same GPU model the published pipeline reports (an Nvidia A40), its receipts are committed beside the winners’, and on that machine the whole checked production of every re-conducted row still completes inside the published wall — with the CPU-proposing lane winning six of the seven Section 2 rows within the A40 receipt set and the seventh within a tenth of a percent. Thus the toolkit’s A40-parity wall does not require its GPU proposer where the published route uses that GPU model. The systems still differ beyond the GPU model, so the table prints no cross-column ratio and the comparison stays qualitative, per section 2.2; the raw walls are the witnesses. On every row with a recorded checked-production wall (the mark-<sup>a</sup> re-conduct cells aside — they time a different job), that whole production now completes inside the published wall, and usually well inside it (*cliff\_crossing*: 1.53 s against a published 153.6 s;

| benchmark                       | best published | certified bound              | ratio                       |

| faulty_walk                     | 0.0121         | $\leq 0.0119293$             | 1.01×                       |
| ↔ deterministic 12-step reading |                | $\leq 0.0119353$             | 1.01×                       |

Ratio-cell tints are the win-tint ladder of section 2.2 (  $\text{light yellow} < 1$  order of magnitude up to  $\text{dark red} 45+$ ); the printed ratio always carries the same information. An ↔ -row's published cell is the row above's. The as-printed faulty\_loop reading has no improvement ratio: the certified exact truth of the printed program exceeds every published column for that row. The persist\_2d gaussian twin — an exact- $\mathbb{Q}$  upper bound of 0.0975251 (rounded up; below both published numbers for the row), its Gaussian integrals discharged through certified enclosures of the error function and exponential in exact interval arithmetic, full drift battery certified, mutant battery (kernel tail-truncation included) refused — entered this table at the row's uniform re-conduct: both twins' verification conditions are re-conducted onto the unified schema of section 2.9 and stored in this repository as sealed shared-subtree containers, every claim re-derived by the fast-path checker with exact per-relation tallies.

Table 2.1: The published-table sweep, all rows. “Best published” is, per row, the minimum over the paper's sound columns; our bounds are certified exact- $\mathbb{Q}$  upper bounds on reach probability, rounded up at the displayed digit.

repulse100\_2d — the row that ran the other way before the re-conduct, at a 222.0 s campaign production wall — 3.87 s against a published 63.5 s, and 6.41 s checked production on the published pipeline’s own GPU model). That campaign wall was dominated by the leg’s exact ground-truth value computation rather than by certification; the computation now rides the producer’s float-propose / exact-certify tier like every other solve, and the row’s whole checked production is 3.87 s. Beyond that comparison, the table establishes the headline economics of the certificate genre: re-verifying a row costs between milliseconds and about a minute at every trust tier — the far end being the 19,200-obligation gaussian twin’s fast-path replay — which is what makes re-verification a regression test rather than an event.

| benchmark                                | VCs   | best published (s) | checked production (s)           | geolog replay (s)      | qtslab replay (s)                   |

Marks (column definitions and protocol: the “Timing protocol” discussion in the text). <sup>a</sup> produce cell times the toolkit re-conduct of the row’s committed certificate corpus, not fresh synthesis. <sup>c</sup> row not in the certified-checker replay’s stored corpus. <sup>d</sup> the replay covers the row’s stored wave-B subset (fewer files than the VCs column). <sup>e</sup> produce wall is the row’s campaign leg’s, as receipted: a synthesis genus not yet in the toolkit producer. Machine tags name the winning machine and lane (section 2.2).

Table 2.2: Wall-clock walls, published pipeline vs. toolkit production and replay tiers (seconds).

**Timing protocol.** “VCs” counts the row’s verification conditions as committed: drift and nonnegativity-class proof obligations, one sealed file per condition per piece or step of the state space, each discharged as a Bernstein Logic proof. Under the unified certificate schema of section 2.9 these become proof nodes inside one sealed certificate per *claim* (a row’s corpus may certify more than one claim — e.g. both readings of a noise model the benchmark’s definition leaves unpinned), so the column counts proof obligations, not certificates. For the persist\_2d twins the count is the committed containers’ summed tree totals (4,800 uniform; 19,200 gaussian): that row’s corpus lives in the re-conduct lane’s sealed containers rather than the staged per-file corpus. “Best published” is seconds as published (learning on an Nvidia A40 GPU plus Z3 verification; the Farkas column is their linear baseline’s LP), for the route attaining the row’s best sound bound — the same selection rule as Table 2.1; transcription provenance rides the repository’s manifest. “Checked production” is, for the re-conducted rows, the toolkit producer’s whole elapsed wall — fresh exact synthesis (float-proposing, exactly certifying, with iterative refinement and continued-fraction reconstruction), listing generation, emission through the geolog engine with the in-loop check, deterministic sealing, and orchestration overhead. For each benchmark, tables/gen\_tables.ts selects the minimum median across all committed machine/proposer-lane receipt sets; the cell tag names the winning machine and lane. The A40 receipts remain separately committed for the GPU-model-parity comparison. Every measured repeat must emit bytes identical to the committed corpus. Versioned Section 1 receipts use their authoritative measured wall\_s; legacy Section 2 receipts use the sum of their disjoint produce\_s,

check\_s, and seal\_s subphases. The gb10-quiet tag is the same GB10 hardware under a quiet-conditions protocol, preregistered before its first campaign ran (the protocol file is committed beside the receipts): the runner itself refuses to start unless the box's 1-minute load average is at or below a declared gate, the campaign is pinned to performance cores at a fixed absolute niceness, and its version-3 receipt records the gate, per-row load averages, and the affinity and niceness read back from the process, so the admission claim is checkable from the receipt alone — the receipt validator refuses a receipt whose recorded starting load exceeds its own declared gate. The load-uncontrolled gb10 receipts remain committed beside the quiet family; where both exist, the minimum-median rule above selects the quieter conduct, and the two are protocol variants of one machine, not different hardware. Rows not yet re-conducted keep their campaign legs' synthesis wall as receipted (single CPU box), and their cells flip the same way as their re-conducts land (section 2.9).

The persist\_2d produce cells (mark <sup>a</sup>) are the one deliberate exception to the fresh-synthesis reading: the twins' certificates are a synthesis genus the toolkit producer does not yet cover (the same gap note <sup>e</sup> records for repulse100\_uniform), and no synthesis wall is receipted in this repository, so those cells time the toolkit's *re-conduct* of the row's committed corpus — shared-subtree forest merge, the in-loop check, and deterministic sealing, byte-identical to the committed containers on every repeat — under the same repeat protocol as the other produce cells (one flagged warmup plus ten measured repeats, serial, medians, at recorded scheduler niceness read back from the process). They are production-tier walls for the stored row, not job-for-job counterparts of the published column, and the chapter draws no such comparison for that row.

“Geolog” is the geolog fast-path checker's total wall over the row's sealed containers, serial, one process at a time (machine, load, and checker-binary hash in each timing receipt). For the re-conducted rows the wall is over the row's shared-subtree containers — proof hypernets: structurally shared subtrees stored once, element in-degree above one, with per-container tree and stored-node counts in the committed manifest — one container per row, except that persist\_2d's gaussian twin ships as four sorted-quarter containers (its merged forest exceeds the envelope's per-commit body cap) and its cell is the serial total of the four per-container medians, its uniform twin one whole-twin container; the pre-migration cells time per-obligation container sets; “VCs” counts proof obligations either way. The two vintages also amortize process overhead differently: a shared-container cell is the median of single-container invocations, each paying the checker's whole per-process vocabulary derivation, where a pre-migration cell spreads one process start across its whole batch. On the shared containers the marginal re-check inside a warm checker process is 5–9 ms on the cells' machine — the same magnitude as the production loop's in-process check — with most of the balance being the per-process vocabulary derivation (the checker's own timing decomposition measures it directly at 44–54 ms there, the remainder being generic process start); one process checking all three shared containers as a batch clears the whole roster in  $\approx 81$  ms, against  $\approx 224$  ms summed per-invocation. The checker-protocol comparability receipts beside the retiming receipts measure both effects with the same checker binary on both container vintages, and an independent-machine replication on a second architecture reproduces the marginal-vs-derivation relationship (and byte-identical containers) while every absolute wall scales with the box, so these milliseconds carry their machine tag rather than traveling as platform constants. Geolog cells are therefore read each under its own protocol, never ratioed across vintages. “Qt slab” is the sum of the certified checker build's per-VC walls from the replay census of section 2.3.1 (Arm cores; four families ran concurrently, so these walls carry mild concurrency inflation at most). The certified checker checks the Bernstein Logic fragment of QTSL only — exactly the proof tower committed as theories/BernsteinLogic.geolog in the pinned qtsl repository, so the fragment boundary is a file boundary, not a convention — and that is the fragment this campaign's VC files natively encode, so the walls shown are complete for the rows they cover. The full QTSL theory (theories/Qtsl.geolog, extending that tower) is checked in geolog, on the sealed-container lanes of section 2.9. The reproduction spine's design also names a certificate-extraction pathway, from a full QTSL certificate down to its Bernstein Logic obligations — the same claim-reducing role the route's other reducers play — and that tool's wall-clock joins this column when it lands. The replay census also predates the shared-subtree vintage: its walls time the stored per-obligation wave-B corpus, and the shared vintage's certified re-check joins this column when the checker build's pin vintage advances. Rows whose containers entered this repository after that census's corpus was pinned — the persist\_2d twins among them — carry mark <sup>c</sup> (not in the replay's stored corpus; they enter at its next replay), and mark <sup>d</sup> rows' replays cover their stored wave-B subsets, fewer files than the VCs column. Mark <sup>e</sup>, in full: repulse100\_uniform's certificate is a different synthesis genus (a continuous-noise, piecewise-polynomial profile) not yet ported into the toolkit producer, so its

produce wall is its campaign leg's, as receipted.

Two findings from this campaign shaped everything after it. First, the exact computation *refuted* one published number: the paper's manually-constructed Farkas bound of 0.0181 for `faulty_uniform` lies strictly below the true reach probability, which the campaign localized to the two-sided interval [0.0184458, 0.0185556] — a published “sound” bound that is not sound, detectable only because the replacement pipeline is exact. Second, re-verification is cheap enough to be a regression test. A row's proof is not one file: it decomposes into per-obligation verification conditions (VCs) — drift and nonnegativity-class obligations, one file per condition per piece or step of the state space — so the seventeen rows fan out to 28,569 VC files, alternate reconstructions and duplicate certifications included. 24,000 of these sit behind the one continuous-state row, certified piecewise on rational lattices under both readings of a noise model the paper leaves unpinned. The full corpus has been replayed through three successive checker builds to date — every file through every build, zero refusals, no bound moved — so the campaign's results are re-established, not merely remembered, at each toolkit revision.

**What is not claimed.** Table 2.2 prints no speedup ratio: the pipelines are compared job-for-job, and the produce, geolog, and qtslab cells each carry the best measured configuration across the repository's timing machines (the machine named in the cell's tag), while the GPU-model-parity receipts — the same GPU model as the published pipeline's, not the same host, driver stack, or whole system — are committed beside them; so any ratio a reader forms still carries a hardware caveat, and the chapter's own statements stay qualitative, per section 2.2. The comparison covers all seventeen published rows, with two cell-level caveats. The `persist_2d` produce cells time the row's re-conduct, not a fresh synthesis (mark <sup>a</sup>: that synthesis genus is not yet in the toolkit producer and no synthesis wall is receipted in this repository, so no job-for-job produce comparison is made for that row), and its certified-checker cells await the replay census's next corpus pin (mark <sup>c</sup>); one re-conducted row's produce wall is still its campaign leg's (note <sup>e</sup>). Nor was every toolkit wall always small: the campaign's one heavy re-check was `persist_2d`'s pre-re-conduct fast-path record of 130.66 s over the row's original 4,800-file uniform bundle — large-denominator rational arithmetic; the stored re-conduct rides the dyadic re-emission that retired those denominators, bound bit-identical, and the row's shared-container replay walls now sit in the table like every other row's.

### 2.3.1 The stored corpus through the certified checker build

The replays above all ride the toolkit's engineering-grade lanes — the reference checker and its fast-path twin. The Executive Summary names a third consumer of the same bytes with a far smaller trust footprint: `qtslab`, the certified checker, whose standing as a whole is stated there once — a demonstrated route, assembling now — and is not upgraded by anything in this subsection. What this subsection adds is a measured fact about that route's current build.

On July 23, 2026, the campaign's stored corpus — the 4,105 VC files behind eight rows of Table 2.1 (six published benchmarks and two alternate readings), each pinned by hash in the repository's manifest — was replayed through the current certified-checker build: a standalone Arm binary emitted inside HOL4 through the CakeML verified compiler, carrying a machine-code theorem, re-proven at this same emission, that a run of the emitted code printing `ACCEPT` with a sequent implies the checker function *defined in the logic* accepts those bytes with that sequent. (That theorem is the route's lower half — the machine code can no longer misrepresent the checker it implements; the upper half, from logical acceptance to semantic truth, is the part still assembling. The truth in question is validity of the accepted sequent under every admissible valuation of the hypernet the certificate itself declares — the Bernstein Logic fragment, which is all this checker's input format carries. The boundary is the checker's, not the vocabulary's: a claim that a System satisfies a Spec is representable today — the full QTSL theory of section 2.9, whose rows the engine-side container lanes check — but it lies outside the certified checker's fragment, and a certificate reaching beyond that fragment is refused, never silently accepted.) The build accepted 4,105 of 4,105 — zero divergence from the fast-path twin, which accepts the same 4,105 — at a pooled median of 30 ms per VC file on one Arm core (min 14 ms,  $p_{90}$  37 ms, max 117 ms). Table 2.3 gives the per-family split; the verdict-by-verdict census, the twin verdicts, and the artefact hashes are committed beside the corpus (`supermartingales/out/sec2/certified-checker/`).

**What is not claimed.** This table reports verification results about committed artefacts; it is not the claim that the finished certified checker exists — the front matter's one-sentence standing governs, and

| family                      | accepted, certified build | diverging vs. fast path | wall per VC file (ms), min/med/ $p_{90}$ /max |
|-----------------------------|---------------------------|-------------------------|-----------------------------------------------|
| cliff_crossing              | 1105/1105                 | 0                       | 17 / 20 / 25 / 55 ms <sup>gb10</sup>          |

| repulse100_2d               | 2267/2267                 | 0                       | 17 / 19 / 21 / 51 ms <sup>gb10</sup>          |
| repulse100_uniform          | 205/205                   | 0                       | 13 / 52 / 85 / 96 ms <sup>gb10</sup>          |
| repulse100_uniform_discrete | 207/207                   | 0                       | 12 / 14 / 15 / 17 ms <sup>gb10</sup>          |
| all families                | 4105/4105                 | 0                       | 11 / 19 / 23 / 96 ms <sup>gb10</sup>          |

Table 2.3: The stored corpus of VC files replayed through the certified checker build (July 23, 2026). “Accepted” is the certified binary’s accepts over the family’s stored VC files; “diverging” counts VC files on which the certified build’s verdict differs from the untrusted fast-path twin’s — zero everywhere, which is the finding. Walls are single-shot, one single-threaded checker process per VC file, four families run concurrently; a serial spot sample ran 10–50 ms, so the concurrency inflates the walls mildly at most.

the numbers here neither strengthen nor presuppose it. The corpus is the eight table rows whose VC files have migrated into this repository, not the full row set. The walls are measured under the mild concurrency stated in the caption, on the machine named in the receipts, and will drift with hardware like any wall-clock. Finally, the certified build itself and the tool that seals row listings into its signed-commit input form have not yet migrated into the public trees: today the table re-derives mechanically from the committed receipts, and re-running the binary replay itself becomes a repository make target when those artefacts land (per the migration rule stated in section 2.9).

## 2.4 Gymnasium: first certified rows for a standard RL suite

The second campaign marched the same machinery across Farama’s Gymnasium — the de-facto standard reinforcement-learning benchmark suite — pinned at repository revision 4347ce947, with every certificate naming its environment id and keyword arguments. To our knowledge, no prior certified bound at any of this chapter’s claim classes has been published for any Gymnasium environment; the comparison points that exist are the suite’s own registered “solved” thresholds and code-comment optima, plus empirical leaderboard numbers, and the campaign’s rows are therefore firsts at their class.

One property of these certificates deserves stating before the table, because every row reads differently in its light: they are *constructive*. Each certificate ships the policy itself — a lookup table, indexed by state and step, sitting in the certificate bytes beside the value table and the claim — so no row asserts merely that a policy achieving the bound *exists*; it asserts that *this* one does, and whoever holds the certificate holds the policy. The checker enforces the distinction structurally: its per-step obligations bound each state’s value by the kernel-weighted value of the shipped policy’s own action — never by a maximum over actions — so the policy is load-bearing in every obligation it discharges, and a tampered policy entry is among the refused mutants of the battery. Table 2.4 is the master table for the tabular tier.

Four findings come out of this table.

**The suite’s own Taxi threshold is unsatisfiable.** The registry declares Taxi “solved” at average return 8, with a code comment placing the optimum at 8.46. The true optimum of the pinned environment is exactly  $793/100 = 7.93$  — *below* the threshold; no policy can meet it. The 8.46 is a fossil: on the pre-correction map (before an upstream fix added one wall segment) the same exact computation yields  $2539/300 = 8.4633\dots$ , which we reproduced by swapping only the map. The threshold was never updated for the wall.

**The first exact value for the textbook blackjack.** Sutton and Barto’s blackjack variant (infinite deck, dealer stands on all 17s, hit/stand only) may be the most-reimplemented exercise in reinforcement learning; a literature search — the textbook, Baldwin et al. 1956, the gambling-mathematics

| environment                   | claim | certified bound      | vs. optimum                | check                           |
|-------------------------------|-------|----------------------|----------------------------|---------------------------------|
| FrozenLake 4x4 (slippery)     | U3    | $\geq 0.7441902$     | optimal, exactly           | $15 \mu\text{s}^{\text{gb}10}$  |
| FrozenLake 8x8 (slippery)     | U3    | $\geq 0.9132201$     | optimal, exactly           | $100 \mu\text{s}^{\text{gb}10}$ |
| FrozenLake 4x4 (succ. 3/4)    | U3    | $\geq 0.8731132$     | optimal, exactly           | $15 \mu\text{s}^{\text{gb}10}$  |
| FrozenLake 4x4 (not slippery) | U3    | $= 1$                | optimal, exactly           | $13 \mu\text{s}^{\text{gb}10}$  |
| Cliff Walking                 | U2    | $\geq -13$           | optimal, exactly           | $24 \mu\text{s}^{\text{gb}10}$  |
| Cliff Walking (slippery)      | U3    | $\geq -63.0133733$   | optimal, exactly           | $34 \mu\text{s}^{\text{gb}10}$  |
| Taxi                          | U2    | $\geq 7.93$          | optimal, exactly           | $0.50 \text{ ms}^{\text{gb}10}$ |
| Taxi (rainy)                  | U3    | $\geq 3.9545745165$  | within $3 \times 10^{-14}$ | $0.70 \text{ ms}^{\text{gb}10}$ |
| Taxi (fickle passenger)       | U3    | $\geq 8.38$          | optimal, exactly           | $1.1 \text{ ms}^{\text{gb}10}$  |
| Taxi (rainy + fickle)         | U3    | $\geq 4.5756463469$  | within $3 \times 10^{-14}$ | $1.5 \text{ ms}^{\text{gb}10}$  |
| Blackjack (S&B rules)         | U3    | $\geq -0.0431131055$ | optimal, exactly           | $0.16 \text{ ms}^{\text{gb}10}$ |

Table 2.4: Certified rows for the Gymnasium tabular tier. The claim column names the species of section 2.1: U2 is a certified cost-to-goal, U3 an exact probabilistic bound. Policies are shipped lookup tables; checks are single-core medians. “Optimal, exactly” means the bound is the exact optimum of the (deadline-truncated) environment: terminal at its claim class — those cells carry the exact-cell tint of section 2.2.

literature, recent preprints — found no published exact expected value under optimal play. It is  $-3954908734551683826282634489/13^{26} \approx -4.311\%$ , now with a machine-checkable certificate. (Consistency: the same game with 3:2 naturals is known to run near  $-2.42\%$ , and the difference is the order of the forgone bonus. A subtlety: the suite’s observation space cannot distinguish a two-card 21 from a three-card 21, but the payout rule can — the certificate runs on a slightly enriched state space while proving the shipped policy never uses the extra information.)

**Hidden state, certified honestly.** Taxi’s “fickle passenger” variant re-draws the destination mid-trip with probability  $3/10$ , invisibly until it fires. A certificate on the full state would be clairvoyant; these rows certify the *belief* chain instead, so the shipped policy is implementable from the observation history. The variant also *raises* the optimum (dry  $7.93 \rightarrow 8.38$ ; rainy  $3.9546 \rightarrow 4.5756$ ): a uniform mid-trip re-draw is on average favourable, and the certified policies exploit the re-route.

**The registry’s comment optima were truncations of numbers nobody had.** The FrozenLake comments say “optimal average reward  $0.74 / 0.91$ .” The exact optima — rationals with denominators  $3^{99}$  and  $3^{200}$  — were computed here, we believe for the first time; the comments are truncations of them.

#### 2.4.1 How the rows were produced: exact backward induction and its wall-clock cost

The producer strategy for the whole tabular tier is the classical algorithm, executed exactly: backward induction — finite-horizon dynamic programming — over the deadline-truncated chain. Starting at the deadline and stepping backward, the producer computes, for every state at every step, the optimal value by a single Bellman backup — a maximum over actions of the expected one-step reward plus the kernel-weighted value one step ahead — in exact rational arithmetic, recording a maximizing action as it goes. The recorded actions *are* the shipped policy; the value tables become the certificate’s obligation rows; the value at the initial state (or the exact mixture over the initial distribution) becomes the claim. Termination and exactness are structural: the horizon is finite — the deadline is the environment’s own truncation, or the certificate’s declared one — the state and action sets are finite, and no backup ever rounds, so after  $T$  sweeps the result is the exact optimum of the truncated environment, not an approximation to it. There is no learning loop, no convergence tolerance, and no rounding anywhere in the construction. (Making exactness fast is an implementation matter, not an algorithmic one: values at each step are stored as integers over a shared power of the kernel denominators’ least common multiple, so the hot loop is integer multiply-accumulate, division-free, with canonical reduction deferred to emission.) Nor is tightness taken from the producer on trust: for the exact lanes the checker has an optimality mode whose obligations quantify over *all* actions — a supersolution check beside the shipped policy’s attainment — so “optimal,

exactly” in Table 2.4 is itself a machine-checkable statement, and the mode’s test fixtures include a matched pair exhibiting the gap: a certificate that passes as a bound but refuses as an optimum.

The direct answer to “how long does producing the optimal policy and its certificate take” is: for the entire tabular catalogue — all 53 certificates, the master table’s rows and the frontier studies’ variants below included — the optimized producer runs from process start to every certificate synthesized, emitted, and byte-compared in 0.69 s of wall-clock time on four CPU cores. The per-lane receipts break that down: the heaviest single computation, the exact optimum of the rainy fickle-passenger Taxi belief chain, takes 117 ms on one core (35 ms on four); the 8x8 FrozenLake exact table, 6.6 ms; the textbook-blackjack optimum, 2.2 ms. The reference implementation that first produced the corpus takes roughly 3.2 s single-core for the same spans; the optimized producer takes 0.5 s on one core (6.5×), and the two emit byte-identical certificates on all 53 — the strongest available cross-implementation check. A GPU lane reproduces the dyadic tables bit-identically with a  $\sim 2\times$  gain on the largest rows only; on small rows the kernel-launch floor loses to the CPU, a null result recorded as such. Throughout, producer cost and check cost are measured separately: the check columns of every table in this section time only the checker.

These certificates also ride the sealed-container lanes of section 2.9, and their re-emission on the unified schema returned a finding rather than a formality. The schema’s chain species is a pure discrete-time Markov chain — transition and initial rows, no action layer — so a hitting-lane certificate carries over verbatim, table and claimed bound alike, exactly when the decision problem admits a *stationary* composition: one action per state admissible at every step of the deadline. The hitting corpus splits 9/29 on that criterion, and the split is semantic content, not an artifact: every deterministic-dynamics certificate composes, while slippery FrozenLake at long deadlines has states where no single action is admissible at every step — near the deadline the optimal policy gambles where far from it it detours. The nine composable certificates already ride the unified schema with their tables and claims byte-verbatim; the twenty time-varying ones stand in the pre-unification record, each exclusion a manifest fact naming its obstructing states, and their re-emission awaits the schema’s decision species (make gymnasium-glc re-checks both lanes and the exclusion records alike).

## 2.4.2 The measured frontier: bound versus check cost

Because the tabular certificates are terminal in bound, the interesting curve is in the *representation*. Two honest knobs trace it: the deadline  $T'$  (certifying “goal within  $T'$  steps” for  $T' \leq T$  weakens the bound but shrinks the table) and the precision  $k$  of a dyadic re-emission (round-down integer tables with bound loss  $\leq T \cdot 2^{-k}$ , turning every obligation into an integer comparison). On the FrozenLake rows, moving from exact rational arithmetic to dyadic integer tables at equal obligation count speeds the check by roughly  $400\times$ – $1400\times$  at a bound cost of order  $10^{-13}$  — far below any displayed digit. The general lesson, confirmed three independent times in this campaign’s receipts: *certificates should be engineered for their checkers* — rationals belong in the claim line, shared-denominator integer slabs in the obligations, and the checker’s hot loop then vectorizes (the kernel-level lanes add a further  $1.6\times$ – $3.3\times$  on the larger reward tables, at 5–7 ns per obligation).

Honest non-dominations in the same receipts: on the smallest certificates the vectorized lane’s setup cost makes it  $0.83\times$ – $0.89\times$  the plain lane (crossover near the 8x8 scale); and one certificate family (blackjack at high dyadic precision) structurally exceeds the vectorized lane’s overflow envelope, is declined, and falls back to the reference lane — deferral costs completeness, never soundness, and the fix is a smaller  $k$ .

## 2.4.3 Beyond tables: continuous state and solver-semantics environments

Above the tabular tier the campaign is deliberately breadth-first, and at this preview two further tiers carry rows.

**Continuous state: certified worst-case return.** The first continuous-state row certifies Pendulum-v1: a Bellman-supersolution certificate over a polynomial cell cover of the state space (the environment’s velocity clipping entering as explicit piecewise structure), yielding a certified *worst-case* return bound: one holding for every initial state, with no probability anywhere in the certificate — the strongest of the claim species of section 2.1 (U1) — and carrying an anytime cover-refinement curve measured from a few dozen cells to nearly a thousand. At this preview the certified bound stands at return  $\geq -1.192$  over the full initial set, with the cover-refinement gap driven to  $2.4 \times 10^{-4}$ , and a five-mutant battery refused.

The corresponding CartPole certificate (worst-case return exactly 500, the same species) has crossed the composition step it was staged behind — and the step dissolved rather than being climbed: instead of transporting a continuous-time decrease certificate through the environment’s explicit-Euler step map, the certified row states a per-cell contraction on the step map itself, which denominator-clears to a polynomial of its own, leaving only kernel-checked enclosures of the current state’s sine and cosine. The first certified CartPole row now stands at the subsystem where it is honest: under an exhibited cell-table bang-bang policy, the pole angle provably never reaches the termination threshold, from every initial state in the reset box, in exact rational arithmetic, with a designed-locus mutant battery refused. The return bound itself still waits on the cart-position excursion, which the pole-only policy does not regulate; that full-state variant is the campaign’s first genuinely large checking workload ( $10^6$ – $10^7$  polynomial cells), sized to exercise the batched checking engine of the Geolog tier as it lands.

**Solver-semantics environments: i.i.d. confidence bounds.** Where the environment’s dynamics is a compiled physics engine (the Box2D and contact-rich MuJoCo families), no analytic species reaches the binary’s semantics, and pretending otherwise would be a category error. What applies instead is the *i.i.d. tier*: an anytime-valid lower confidence bound on the expected return, certified from recorded rollouts of a pinned policy — the weakest species of section 2.1 (U5), holding with probability at least  $1 - \alpha$  rather than almost surely, but model-free, which is exactly what lets it reach a compiled binary at all. Its rows are always displayed as their own class, never mixed into a table of exact rows: Table 2.5 shows the first two — to our knowledge the first certified statements of any kind at this claim class for Box2D environments. Each is a betting-martingale ledger over  $10^6$  rollouts of the suite’s own heuristic controller; the checker re-verifies the entire wealth process in directed-rounding fixed point ( $1.6 \times 10^7$  obligations in  $\sim 130$ – $200$  ms, single-core), and the certificate is *anytime-valid*: extending the ledger with more episodes can only tighten the bound, with no statistical penalty.

| environment              | claim (class U5)                     | bound | threshold |
|--------------------------|--------------------------------------|-------|-----------|
| LunarLander-v3           | $\mathbb{E}[R] \geq, \alpha = 1/100$ | 236.2 | 200       |
| LunarLanderContinuous-v3 | $\mathbb{E}[R] \geq, \alpha = 1/100$ | 281.1 | 200       |

Table 2.5: First i.i.d.-tier rows (species U5 of section 2.1; confidence-qualified: each bound holds with probability  $\geq 1 - \alpha$  over the sampling; never to be read as almost-sure). Policies are the suite’s own heuristic controllers;  $n = 10^6$  episodes each; the almost-sure return range required by the bound is itself a certified lemma about the environment’s code, not an assumption. Bound-cell tints are the win-tint ladder of section 2.2, read against the registry threshold beside them.

One reading of Table 2.5 previews the genre’s point: the *certified floor* of the continuous-throttle variant (281) exceeds the discrete variant’s *empirical mean* (238) — a policy-comparison statement made entirely below the certified line, where it cannot be an artefact of sampling luck.

**What is not claimed.** The tabular certificates’ trust seam — that the modelled kernel is the environment’s — is narrowed here by asserting the modelled tables equal to the suite’s own published transition tables (exact equality, with the handful of float-literal discrepancies carried as declared ledger rows), but it remains producer-side. The i.i.d.-tier rows trust the pinned pseudorandom generator and the policy’s determinism, both named in the certificate. No worst-case, cost-to-goal, or exact-probabilistic claim (species U1–U3) is made for any solver-semantics environment. No MuJoCo row appears in this preview’s tables; the named route — its design landed as this preview goes to press, rows in flight — is a hybrid-time composition pattern: discrete controller ticks with bounded clock jitter coupled to continuous-time physics, the jitter entering as a certificate *parameter* rather than a disturbance, with the suite’s contact-free environments (InvertedPendulum and its ladder) as first targets and the contact-rich families expected to arrive i.i.d.-tier first. Producer-side synthesis time for the continuous tier is reported in the repository but not compared against reinforcement-learning training costs: the claims differ in kind, and a wall-clock race between them would compare nothing meaningful.

## 2.5 Hardware model checking: certificates where verdicts were

The third campaign targets a benchmark from a different community: the hardware model-checking suite introduced by the neural model-checking line of work (Giacobbe, Kroening, Pal, and Tautschnig, *Neural Model Checking*, NeurIPS 2024, arXiv 2410.23790) and extended by the same group at NeurIPS 2025 (*Let a Neural Network Be Your Invariant*) — eleven Verilog designs (UART and I<sup>2</sup>C controllers, VGA and LCD drivers, PWM, counter, and thermocouple-interface blocks), each with a ladder of parameter instances, under three property classes: 219 pure-liveness tasks ( $\text{FG } \alpha \rightarrow \text{GF } \beta$ ), 206 safety tasks, and 209 combined safety-plus-liveness tasks (premise-guarded until-properties such as  $\text{G}(r \rightarrow p \cup q)$ ) — 634 verification tasks in all. The published pipelines train a neural certificate per task — a ranking function by gradient descent in 2024; ranking and invariant functions by MILP in 2025 — quantize it, and hand a single validity query to an SMT solver; the reported verdict per task is the solver’s “unsat.” The baselines are mature model checkers (nuXmv, ABC, rIC3), and the experimental budget is five hours per task.

The toolkit’s route is structurally different, and the difference is the point. Every one of the 634 specifications reduces, by a chain of temporal rewrite steps, to conjunctions of two certified forms: pure recurrence  $\text{GF } \gamma$ , discharged by a ranking function — piecewise-affine with exact rational coefficients over a cell partition of the circuit’s own branch structure, input wires resolved demonically (universally) at every step — and  $k$ -step safety windows, discharged by obligations on the exact one-step image (plus small inductive invariants on the four families that need them). No Büchi automaton and no product construction appears anywhere on the suite. The trust story is layered the same way at every level: the consuming lemmas (a ranking that drops by  $\varepsilon_0$  off the target and stays nonnegative forces target steps to recur; a window whose obligations hold on the reachable image holds always) are a few lines of mathematics each, machine-checked in Lean with no measure theory; every rewrite rule’s soundness is machine-checked *twice*, in Lean and independently in HOL4; each task carries a rewrite-chain witness that a standalone checker replays from the verbatim specification text; and every ranking and window condition is an ordinary polynomial-nonnegativity row of the chapter 15 calculus, recomputed exactly in  $\mathbb{Q}$  by standalone checkers that import nothing from the producers.

At this preview the sweep covers the entire suite: **all 634 tasks, across all three classes** — 219/219 pure liveness (245 certificates: the two conjunction families carry two per task), 206/206 safety (222 certificates), and 209/209 safety-plus-liveness (418: one window and one recurrence certificate per task) — 885 certificates and 634 chain witnesses in all. Table 2.6 sets this against the published field on the field’s own numbers: the strongest single published tool, the 2025 MILP method, completes 554 of 634; the per-task union of *every* tool in the 2025 paper’s comparison completes 617. Seventeen tasks are completed by nothing published at all — twelve pure-liveness tasks (eleven blink instances and the largest `load_store` instance) and the five largest blink safety-plus-liveness tasks. The toolkit certifies all seventeen; blink is a counter ladder, and its certificates have the same shape at  $N = 2^{32}$  as at  $N = 2^8$ .

Three anchoring notes travel with Table 2.6. First, *the comparison is like-for-like with the 2025 paper* and only approximately comparable to the 2024 publication: the benchmark’s circuits were revised between the two editions (142 source files changed semantically, an edit the 2025 paper does not mention), and the toolkit certifies the revised circuits — the same files the 2025 re-runs measured. The 2024 method’s own line shows the drift: 93% of its original 194 tasks as published, on the 2024-era circuits; 172/219 under its authors’ re-run on the revised, extended class. Second, *the semantics certified is the benchmark’s exactly*: the suite’s generated SMV models carry no initial-state constraint, so every task is a from-every-state claim under demonically-resolved inputs — precisely the universal form the certificates prove. For the until-shaped class this was additionally confirmed off-calculus: an independent explicit-state model checker (a demonic greatest-fixpoint computation written against the specification semantics, not the certificate calculus) verifies each safety-plus-liveness property as stated on the smallest instance of every family, and falsifies none. Third, *the completion race is not the durable claim* — model checkers are healthy, and successor methods will contest counts. The durable column is the last one: on this suite, every completed task ships an auditable certificate, a small exact object whose consuming lemma is machine-checked, where every baseline — neural or classical — ships a verdict.

The checking economics stay flat as the suite triples. Certificates run 0.4–7.4 KB (98% under 4 KB; the tail is the VGA safety windows); individual checks run from tens of microseconds to a few milliseconds; replaying every certificate *and* every rewrite-chain witness in all three classes takes under a second of single-core wall-clock in total (per the class receipts: certificate checks of 78, 195, and 171 ms for liveness,

| method                        | liveness 219 | safety 206 | s+l 209 | all 634 | per-task evidence     |
|-------------------------------|--------------|------------|---------|---------|-----------------------|
| this toolkit                  | 219          | 206        | 209     | 634     | checkable certificate |
| neural, NeurIPS'25 (MILP)     | 192          | 190        | 172     | 554     | solver verdict        |
| nuXmv (BDD)                   | 180          | 206        | 154     | 540     | tool verdict          |
| rIC3 1.5.1                    | 110          | 196        | 129     | 435     | tool verdict          |
| ABC                           | 78           | 206        | 96      | 380     | tool verdict          |
| neural, NeurIPS'24 (re-run)   | 172          | n/a        | n/a     | 172     | solver verdict        |
| virtual best of all baselines | 207          | 206        | 204     | 617     | portfolio of verdicts |

Table 2.6: The full NeurIPS'25 neural-model-checking suite: completions by property class (pure liveness 219, safety 206, safety-plus-liveness 209). Baseline counts are recomputed from the 2025 paper's own artefact — its plotting script's hard-coded runtime arrays are the paper's published data — at the paper's own five-hour timeout. The 2024 method is a liveness-only technique; the artefact records no runs for it outside that class (n/a). The virtual-best row is the per-task union of every baseline in the artefact's comparison, including the linear variant of the 2025 method, which is not shown as a separate row. The toolkit's per-task evidence is an exact-arithmetic certificate replayed by a standalone checker, with consuming lemmas machine-checked in Lean and every spec-rewrite rule machine-checked in both Lean and HOL4. A toolkit count carries the exact-cell tint of section 2.2 where it strictly exceeds the virtual best of the whole published portfolio (ties untinted).

safety, and safety-plus-liveness, plus 82, 118, and 150 ms of chain replay). Certificate size and check time are constant along each design's parameter ladder, with only coefficient widths growing as  $\log N$ , where the learning pipelines pay training and solving per instance. Per the conventions of section 2.2, the two sides' times are a contrast of kind, not a ratio — searching for a proof and re-verifying a shipped one are different jobs on different machines: the paper reports a five-hour-per-task budget and roughly nine thousand machine-hours for its full experimental campaign; the toolkit's whole-suite certificate replay is the under-a-second figure above.

Refusal is exercised as systematically as acceptance. Each class ships a mutant battery — deliberately corrupted certificates and chain witnesses, each designed to be refused at one specific check: seventeen layer-targeted attacks with four positive controls for the liveness class (ported into this repository's re-check driver), thirteen attacks with three controls for safety, and fourteen attacks with nine controls for the combined class, two of those attacks cross-layer (accepted by the certificate checker, refused by the chain checker) — and each is in fact refused at the attacked layer, with every control passing. The remaining producer-side trust seam is the circuit manifests: that the certified step system *is* the Verilog's semantics. It is narrowed by two-simulator cross-checks, exhaustive on the full state-input box of each family's smallest instance and sampled on the largest, and — since the safety campaign — by an independent re-transcription of every design. That newest instrument earned its keep immediately: the two original simulators share an author, the first edition of this section said so as its declared residue, and the re-transcription caught exactly the failure that caveat named — a shared misreading of one LCD counter's wrap point, latent in the already-swept liveness manifests. The manifests were repaired and the full battery re-run green within the hour; the fixtures in this repository are the repaired ones. Replacing this seam with a netlist-level bridge remains named successor work.

Exact re-derivation of a published field keeps yielding findings of the same genre as the Gymnasium campaign's unsatisfiable Taxi threshold (section 2.4). Three from this campaign are worth recording. *The sound premise is not the obvious one*: the natural liveness premise for the until-introduction rewrite rule —  $\text{GF } q$ , “the window eventually closes” — is false whole-box on the I<sup>2</sup>C family, whose clock-stretch freeze states never reach the window and satisfy  $\neg p$  forever instead; the sound premise is  $\text{GF}(\neg p \vee q)$ . The correction was forced during rule design and then observed semantically: the explicit-state falsifier's demon-winning regions are nonempty exactly on those frozen states. *One task's two specification sources disagree*: the delay design's first combined property reads  $\text{G } \neg rst \rightarrow \dots$  in the runner's specification text but  $\text{FG } \neg rst \rightarrow \dots$  in the same runner's nuXmv property line. The toolkit certifies the specification text as stated — the chain witness pins its verbatim bytes — and records the discrepancy; certifying as-stated rather than as-presumably-meant is what makes such discrepancies visible at all. *The artefact's own aggregation has a slip*: the 2025 plotting script assembles its safety-class aggregate with one VGA family's arrays included twice and the other's omitted. The counts in Table 2.6 are unaffected — they are recomputed from

the per-family arrays, and both VGA safety families are fully solved by the classical baselines — but the paper’s aggregate safety timing figures ride the wrong multiset. (The 2024 edition had a kindred fossil: an appendix table summing to 177 completions where the summary claims 180; the census here restored the three footnoted rows a naive parse drops, scoring that comparison in the paper’s favor.)

Because the producers here are benchmark-specific and written by us, the fair cost question is not only “how fast is the check?” but “what did it cost to *get* the certificates, method invention included?” — and the campaign’s working sessions are timestamped, so it has a measured answer. The pure-liveness campaign end-to-end — reading the papers, designing the route, machine-checking the consuming lemma, writing the certificate format, the checker, and every producer, and sweeping all its tasks — took about 75 minutes of commit-stamped wall-clock on one desk-side machine (this repository’s invention-time comparison table carries the per-phase receipts and its estimating conventions). The safety class and the combined class were each added in a single further working session the following day — the combined class including six new until-introduction rewrite rules, each proved twice, in Lean and in HOL4. These figures sit beside the published five-hours-per-task budget as, again, a contrast of kind: method invention on one side of the ledger is being compared to certificate search on the other, and we print no ratio.

**What is not claimed.** Synthesis wall-clock supremacy is not claimed: on tasks the 2025 MILP method completes, it is itself fast (sub-second on most families); the measured advantages here are completion, the check side, and the evidence class. Generality over automaton-requiring specifications is not claimed: no property in this suite needs genuine automaton memory — the 2025 additions, though until-shaped, reduce by premise-checked implication rules — and on a suite where that machinery is needed, it would return. Sim-tightness is claimed only where measured: every liveness family’s worst-case descent bound is achieved exactly by a simulated run of the circuit. And the reproduction spine in this repository is complete at this preview for the pure-liveness class only — committed fixtures, the pinned independent checker, and the mutant battery, re-run end to end by one make target; the safety and combined classes’ receipt tables are vendored here, and their fixtures and checkers arrive with the producer layer’s migration. Per the preview note of section 2.9, until a cited artefact lands in the public repository, its mention is a statement of what exists, not yet a link.

## 2.6 Atari as a circuit: making the environment white-box

The fourth campaign closes a loop between the previous two. It takes an environment family from the reinforcement-learning suite’s hardest tier — Atari 2600 games, which Gymnasium reaches through an emulator plugin — and turns each game into an object of the hardware campaign’s kind. Rather than treating the emulator as a black box to be sampled, the campaign compiles the console itself into a synchronous digital circuit: an open-source Verilog implementation of the 2600 (vendor-pinned, with three local repairs, each carried in a ledger) is synthesized with the game ROM baked in, down to an and-inverter graph. Pong closes to a circuit with 52 input bits, 1,491 flip-flops, and 20,821 AND gates; Freeway to 52/1,491/20,798; Montezuma’s Revenge — whose 8 KB bank-switched cartridge brings its mapper hardware into the netlist alongside the console — to 52/1,501/36,698. The machines’ full state spaces are  $2^{1491}$  and  $2^{1501}$ .

This is where the scope condition of section 2.1 has its teeth, so it bears restating in this campaign’s terms: the toolkit can actually *examine* the environment’s digital-circuit structure. The transition relation is a given, finite, white-box object, and every claim species of this chapter becomes definable over it — the ranking rows of section 2.5 apply to the environment itself, not to an abstraction of it. System identification — recovering such a circuit from observations of play — is a separate problem, and one the toolkit does not yet have tools for. Nothing in this campaign learns the environment; it is handed the mechanism and reasons about it.

What is landed at this preview is the foundation tier: the compiled circuits and their fidelity receipts. Differential validation runs the circuit and the suite’s own emulator (ale-py) frame-locked, side by side: on Pong and Freeway, episode returns are *identical* — Pong’s rally period is exactly 140 frames on both; Freeway’s first crossing lands on the same frame — and 116–123 of the 128 RAM bytes match exactly on every frame, with each remaining divergence assigned to a named class (an input-transduction mismatch, since resolved by measurement; a one-to-two-frame boot-time skew attributed to the pinned CPU core’s

known non-cycle-exactness) rather than left as noise. One finding from this validation is recorded as a surprise: the emulator’s RAM trace is invariant across its random seeds — for these games, the suite’s stochasticity lives in frame-skip and action timing, not in the machine.

The first certified rows above that foundation landed as this preview closed: exact-replay returns — worst-case over the suite’s full initial-condition randomization, all 31 no-op offsets (species U1 of section 2.1) — for a fixed open-loop policy, certified by a checker whose only dynamics authority is the compiled circuit itself — “this policy scores  $R$ ” turned from a measurement into a theorem about the circuit. Table 2.7 shows the rows. The Freeway row carries a finding: the certified per-offset returns span  $\{2, 3, 4\}$ , so a single rollout of this policy reports a number drawn from the init lottery, and the certified minimum (2) sits strictly below the modal return — the gap between “return of a rollout” and “return guaranteed over the init set,” exhibited concretely.

The last two rows take the same claim species to Montezuma’s Revenge — the suite’s canonical hard-exploration benchmark, the game whose sparse rewards famously held early deep reinforcement-learning agents to a score of zero. To our knowledge these are the first certified return claims for this game at any claim class; every published Montezuma number is an empirical rollout statistic. The certified content is exact: reaching the first key (return 100) is certified at *every* one of the 31 no-op init offsets, and a 1,548-frame trajectory that collects the key and opens a door of the first room is certified at return exactly 400 from the declared initial state — each reward event pinned to its frame, all 128.5 million netlist clock ticks of the replay re-derived by the checker, every frame of the pinned witness traces compared bit-exact. The rows’ structure carries a finding of the Freeway kind, amplified: a committed instrument row certifies that the fixed key script which scores 100 at offset zero scores exactly 0 at every other offset — total collapse under the init lottery, where Freeway’s spread was one point — so the per-offset row holds thirty-one separately searched scripts, one per offset. Transfer fails the same way at finer grain: a script optimized against the reference emulator, where it scores 400, scores only 100 when replayed through the circuit, losing a life at a pixel-perfect skull crossing that succeeds under the emulator’s timing and fails under the circuit’s. Trajectories that certify on the circuit were searched on the circuit; the searcher is producer-side and untrusted, and nothing about how the scripts were found enters the trust story — the certificate is the exact replay.

In flight at this preview: liveness rows over the compiled circuit at the previous section’s claim classes, and policy rows — closed-loop pixels-to-action policies rather than fixed scripts — for the games themselves; toward the latter, the checker has already grown a pixel lane, which on the key trajectory compared every one of the 26,997,440 pixels the game renders across its 706 frames bit-exact against the circuit’s video output. Each will carry the same receipts discipline as every table above.

| environment       | policy                 | $T$  | init set          | min return | check  |
|-------------------|------------------------|------|-------------------|------------|--------|
| Pong              | NOOP script            | 1000 | $k \in \{0..30\}$ | −6         | 1405 s |
| Freeway           | all-UP script          | 1000 | $k \in \{0..30\}$ | 2          | 1410 s |
| MontezumasRevenge | per-offset key scripts | 828  | $k \in \{0..30\}$ | 100        | 3943 s |
| MontezumasRevenge | key+door script        | 1548 | $k = 0$           | 400        | 6416 s |

Table 2.7: Certified exact-replay rows (worst-case species U1 of section 2.1); each environment is the compiled circuit `AtariCircuit-⟨game⟩`. “Min return” is the certified minimum over the row’s declared init set (exact, hence the exact-cell tint of section 2.2) — all 31 no-op offsets, except that the key+door row declares the single offset  $k = 0$ ; the per-offset Montezuma row certifies one separately searched script per offset. Check times are single-core replay of the claim’s own circuit.

**What is not claimed.** These exact-replay rows are the certified ladder’s weakest rung — a fixed open-loop policy, exact replay, no quantification over adversaries and no learned certificate — and their receipts say so; no liveness or policy-optimality claim is stated for any Atari game at this preview. The Montezuma key+door row in particular quantifies over nothing: one declared initial state, one script, 1,548 frames — it certifies that score on that trajectory exactly and is silent about the rest of the game. Nothing here “solves” Montezuma’s Revenge; what is new is that a Montezuma score is carried by a machine-checked certificate against the machine’s own transition relation instead of by a rollout report. The five-to-twelve divergent RAM bytes per frame in the emulator differential are declared, not resolved; the CPU core’s cycle-exactness is a named seam of exactly the circuit-manifest kind (section 2.5); and claims about the

emulator itself rest on the differential receipts alone. The white-box condition above is load-bearing: none of this machinery applies to an environment whose mechanism cannot be handed over.

## 2.7 Process control: the semiconductor ladder

The final campaign leaves benchmarks-with-leaderboards entirely and runs on two tracks over a ladder of semiconductor-fab process models — the application-domain family the toolkit’s programme context cares about, and a domain where the certified claims are economically legible. The *fluid* track instantiates the chapter’s infinite-horizon species (U4 of section 2.1: long-run throughput and stability claims for queueing-network models): *this dispatch policy keeps the line stable at this load*. That claim has teeth because it is famously falsifiable: re-entrant lines destabilize under plausible dispatch policies strictly below nominal capacity (the Kumar–Seidman phenomenon), and the fluid-limit criteria of Dai and Dai–Weiss reduce stability to exactly the polyhedral drift inequalities the toolkit’s checkers replay. The *discrete* track — new at this preview, on the base rung — instantiates the worst-case ranking species (U2, quantified here over every scheduler rather than every initial state): *every dispatch of this line ships all lots by this deadline* — and carries it past any of the chapter’s other campaigns, to a claim class none of them produce: exact optimality, a certified floor over *all* dispatch policies met exactly by a shipped one.

**The ladder, whole.** The campaign’s target is a fixed progression of eleven public fab models in four stages — the Intel Mini-Fab; the seven SEMATECH MIMAC testbed fabs [82]; the two SMT2020 scenario fabs [142]; and SMAT2022 [158] — carrying the same claim species at every rung, so the ladder is a progression in scale and modelled physics, never a change of subject:

| rung          | one-line identity                                       | certified rows |
|---------------|---------------------------------------------------------|----------------|
| Mini-Fab      | 3 stations, 5 machines, 6 re-entrant steps (Kempf 1994) | this preview   |
| MIMAC set 1   | 2 products, 265 tools, routes to 245 steps              | —              |
| MIMAC set 2   | 7 products, 274 tools, routes to 354 steps              | —              |
| MIMAC set 3   | 11 products, 354 tools, routes to 547 steps             | —              |
| MIMAC set 4   | 7 products, 69 tools, routes to 92 steps                | —              |
| MIMAC set 5   | 21 products, 176 tools, routes to 266 steps             | —              |
| MIMAC set 6   | 9 products, 228 tools, routes to 355 steps              | —              |
| MIMAC set 7   | 1 product, 38 tools, one 172-step re-entrant route      | this preview   |
| SMT2020 HV/LM | high-volume/low-mix scenario fab, $\sim 10^3$ tools     | —              |
| SMT2020 LV/HM | low-volume/high-mix scenario fab, $\sim 10^3$ tools     | —              |
| SMAT2022      | the SMT2020 fabs + automated material handling          | —              |

MIMAC set characteristics are the testbed’s own dataset tables, tabulated independently by Zhou and Rose [248]. One count deserves a flag: the testbed’s catalogue prose says *six* datasets, and that count circulates in the citing literature — but set 7 (a synthetic single-product fab adapted from a published model of Lawrence Wein’s) entered the archive days after the catalogue text’s 1997 revision and was never re-catalogued, and the archive itself ships seven. SMT2020’s two scenario fabs each ship with an engineering-lots variant; SMAT2022 extends all four SMT2020 models with a full automated-material-handling layer — vehicles, rails, bays, ports.

The stages differ in which physics must enter the certificate, and that difference is the ladder’s actual content. The Mini-Fab is small enough that every modelling decision can be witnessed line by line — chapter 17 gives the model and this campaign’s certificates a chapter-length reading — yet it already carries the domain’s hard structure (re-entrance, batching, sequence-dependent setups, shared personnel, failures), so the base rung certifies on both tracks: fluid-drift stability with the awkward layers priced by explicit adversarial rows (work-in-progress and cycle-time moments as named successors), and the discrete dispatch campaign, carried at this preview through policy synthesis, wall-clock optimality, and a certified envelope for untrusted policies. The MIMAC stage is the same claim species at real-fab scale, where the sign-mode census dies combinatorially: certifying it means aggregated covers with certified refinement paths, plus an extraction pipeline from the testbed’s 1990s fixed-width dataset format to declared network rows. The SMT2020 stage adds another order of magnitude ( $\sim 10^3$  tools) and a maintained community simulator (PySCFabSim), so analytic rows gain a simulation oracle beside them — anytime-valid statistical confidence bounds (the U5 rows of section 2.1) apply at every rung today and are the honest first deliverable

at the top ones. SMAT2022 adds the transport network itself to the contended resources, and its reference simulator is closed-shape, so the declared model carries the semantics alone.

**Certified today: the Mini-Fab, fluid track.** The base rung's model — the community's minimal re-entrant fab, whose batching, setup, personnel, and failure layers make five machines an honest miniature of the domain — is described at reading depth in chapter 17, which also walks these certificates decision by decision; here, the campaign summary. For the fluid model of the deterministic core, under named static-priority dispatch policies (last- and first-buffer-first-served), with all residual scheduling freedom resolved adversarially: certified linear-Lyapunov drain certificates at release rates up to 95.9 of the 96 lots/week fluid capacity (99.90%), with the checker independently rebuilding every polytope and replaying one exact- $\mathbb{Q}$  Farkas dual per mode — and the probe at 96 correctly failing, because the load is genuinely at capacity: producer-side bisection brackets the last certifiable release within  $6 \times 10^{-5}$  lots/week of the fluid capacity, so the one-lot gap in this campaign's earlier grid was grid granularity, not lost capacity. A setup-adversarial variant (setup times charged worst-case inline) certifies up to 99.8% of its own reduced ceiling. Certificates carry 819 obligations and check in 1–3 ms; the two rows nearest capacity ride fully-refined sign-split tree covers — the refinement species the testbed rung below leans on, exercised first here. The certified drain rates also separate the two policies near capacity — an exact policy-comparison number of the kind this claim species was chosen to produce.

**Certified today: the Mini-Fab, discrete track — dispatch synthesis, to exact optimality.** The same line, read as a discrete transition net (16 places, 19 transitions, 49 arcs; every logistical step one tick), carries a family of twelve certificates — 150 footprint rows of a sealed certificate container: a work-potential ranking budgeting each lot's run at exactly 638 firings, lot conservation, six machine conservation bounds, congestion, a ceiling, and an arrival-potential + step-budget pair yielding the worst-case deadline, *all  $N$  lots arrived within  $638N - 12$  steps*, over every scheduler interleaving. Nothing in the certificate scales with the lot count:  $N$  enters only as three integers in the container's own data, so the same rows instantiate from  $N = 7$  to  $N = 10^7$  with the container growing six bytes across six orders of magnitude and the checker's wall time flat at  $\sim 2$  ms per container — at the top of that sweep the claims quantify over at least  $2 \times 10^{38}$  reachable markings and  $10^{2 \times 10^7}$  distinct maximal schedules, none of which the checker visits. Opening one supervisor seat (the plant re-stated as a comb with a single policy-shaped hole; the hole count is itself a checked claim) turns the deadline into a synthesis instrument: joint policy+certificate search returns a latest-safe-unlock supervisor with certified completion and all arrivals by  $626N$  steps — 52,584 against the 53,580 no-policy worst case at the weekly  $N = 84$ , a certified throughput-floor gain of 1.9%. The synthesis objective is lexicographic — certified completion first, then the horizon — and the order is load-bearing: a gate that never opens ties the arrival optimum and then deadlocks shipping nothing, and the search refuses it at the completion certificate with the starved queue named.

The counting-time story transfers to the wall clock, and closes there. Under the theory's discrete clock semantics (every transition dwells exactly one tick) the same containers reseal with identical row tallies, and the counting bounds become tick bounds by a no-idle argument ( $\leq 626N$  gated,  $\leq 638N - 12$  open). Beneath them sits a floor over *all* dispatch policies of any kind, supervisory or never-idle: no policy reaches all-arrivals in fewer than  $255N + 375$  ticks for  $N \geq 4$  — a machine-contiguity argument proved in Lean 4 over mathlib, with adversarial mutants at preregistered loci refused by the kernel, lifting an arithmetic floor of  $255N + 371$  (verified by exhaustive SMT search below  $N = 8$ , with witness schedules independently re-validated); the exact wall-clock optimum is  $255N + 371 + d(N)$ ,  $d = (0, 0, 2, 4, 4, \dots)$ , closed from both sides at every  $N$ . An explicit supervisor family attains the lifted floor exactly at every tested lot count: 21,795 ticks at  $N = 84$ , per-lot throughput 255 ticks closed from both sides — so the certified-optimality column of the dispatch grid reads 100.00%, earned rather than rounded: a Lean-checked floor meeting a container-replayed attainment at  $255N + 375$  exactly. The grid around it separates the levers. The sixteen never-idle full-dispatch policies deliver 99.63, 75.61, 65.34, and 54.35% of certifiably-unbeatable performance, and only the diffusion-station pull preference ever moves a number; deliberate idling is necessary for the last stretch (the best work-conserving policy needs  $255N + 455$  ticks, 80 behind optimal); and the wall-clock value concentrates in the dispatch seat: an adversarial pull order costs +83.5%, while the synthesized gate — whose value is the certified worst-case floor, a guarantee over every schedule — moves typical-case arrivals 0.0%. Optimality here is also the decision-theoretically right word: with deterministic closed dynamics, imprecise-decision-theoretic policy selection provably collapses to makespan minimization (machine-checked, with a refutation cell showing the collapse fails without determinism).

The track's last exhibit prices the case nobody certifies: an *uncertified* policy — a lookahead heuristic

standing in for a learned dispatcher — filling the same seat behind a certified switching envelope (certified baseline, decision-budget bench, certified recovery region). The envelope’s certificates never read the policy. In replay, the heuristic ran free and attained the envelope’s arrival bound  $638N - 11$  exactly at  $N = 84$ , so the bound is witnessed tight, not merely sound; a deliberate idler was benched at the budget boundary with recovery at exactly 1,009 firings; a rogue policy was benched after eight named in-loop refusals with the plant untouched; and after all runs the sealed container re-verified byte-identical. The whole discrete family — closed baseline, open comb, synthesized supervisor, switching envelope, and the wall-clock reseals of baseline, comb, and supervisor — re-checks from bytes alone by one reproduction target (section 2.9), with committed integrity mutants that must refuse and the producer-tier mutant batteries re-run beside it; chapter 17 walks the model, the synthesis, and the grid at chapter length.

**Certified today: MIMAC set 7, at the cover and one refinement in** (the smallest of the seven by tool count: one product, 38 machines in 24 tool groups, one 172-step re-entrant route). The structural problem at this scale is that mode-by-mode certification is  $2^{172}$ -large; the certificate instead quantifies over an *aggregated cover* — cells whose relaxed polytopes provably over-approximate every sign mode, by a lemma whose only move is dropping constraints (so soundness is monotone by construction). The honest price appears in the bound, and so, now, does the refinement path. At the coarsest cover (172 cells; proven weight-optimal for that cover) the certified stable load is 13.2% of the dataset’s nominal release (availability-adjusted variant: 11.5%). Walking the certificate format’s built-in refinement path (binary sign-split trees, anytime-refinable down to the exact mode walk) — with the weight search and every cell’s dual solved as one sparse linear program — lifts this to a certified  $1964/9903 \approx 19.8\%$  of nominal on a 244-cell tree ( $1.50\times$  the coarsest cover; 84,180 obligations, replayed by the checker exactly like every other row). Both numbers are weak, both are displayed at full prominence, and the certified 19.8% is a floor rather than a ceiling: the refinement run was stopped early, with producer-side bisection already bracketing 23–24% at five times the cells (measured, not yet certified) — and the measured refinement curve is sublinear enough that explicit trees cannot reach nominal load at fab scale, so pricing that species limit, and the implicit-cover species that removes it, is named successor work. The aggregation gap is a measured frontier, not fine print.

**What is not claimed.** On the fluid track these are claims about declared fluid models of the fabs, with batching, setups, and failures handled by explicit adversarial or interval rows where modelled at all — the model gap to the discrete line rides a declared ledger, and the conversion from certified drain rates to work-in-progress and cycle-time bounds on the discrete line (via Foster–Lyapunov moment rows and Little’s law) is named successor work. On the discrete track the claims are exact, but the model sits deliberately in the unit-dwell deterministic corner: zero stochastic species instantiated, so a policy-filled closure has one trajectory per lot count, and the demonic quantifiers live at the family level (the all-policy floors; the envelope over an untrusted filler). Since every certificate quantifies over the full scheduling freedom, its claims dominate every rate-raced refinement of that freedom — the stochastic layers, when they arrive on the higher rungs, resolve freedom the certificates have already priced. An earlier preview of this section stated that no claim was made about optimality of the dispatch policies, only their certified stability region; that sentence is now true of the fluid track alone — on the discrete Mini-Fab the optimality question is closed, floor and attainment meeting at  $255N + 375$  — and the correction is recorded here rather than silently edited away, because the distance between the two previews is itself a result. The ladder’s remaining nine rungs — MIMAC sets 1–6, the SMT2020 pair, and SMAT2022 — are census-scoped but carry no certificates at this preview.

## 2.8 The Lean route: how much Lean?

The toolkit’s third checking path — the last of the three checking routes whose division of labor the front matter states (chapter 1) — loads the same sealed certificate container that every other checker consumes into Lean, reconstructs the claim, and lets Lean accept it as a theorem. The route’s decode, reconstruction, and validity elaboration are ordinary Lean definitions; its acceptance theorem says that anything the route accepts is semantically valid — valid, that is, under every admissible valuation of the hypernet the certificate declares: the same Bernstein Logic valuation semantics the toolkit’s other checkers answer to — and the proof is one line, because the accepted value carries the validity proof built during elaboration. The same definitions are consumed two ways: *compiled*, as a native executable produced by the Lean compiler, and

*kernel*, where a generated receipt module asks the kernel itself to evaluate the entire pipeline over the embedded bytes (*decide*) — no compiler, no extraction, just the trusted evaluator. The route exists to make a measured statement, not a rhetorical one: the expectation has always been that the kernel path is far too slow for machine-scale certificates, and this section measures how far.

### 2.8.1 The ladder

The measurement corpus is a size ladder of fifteen production certificates — sealed containers from the working producer stack, spanning 603 bytes to 126,216 bytes ( $\times 209$ ) across seven certificate families, each rung accepted by the independent reference checker before any Lean timing was attempted. The ladder is committed byte-for-byte in `lean-route/fixtures/`; as elsewhere in this repository, the certificates stand on their own, and no producer is part of the trust story. All timings in this section were taken on one otherwise-idle machine (AMD EPYC 7B13, 16 threads, 126 GiB), single job at a time, with a 10-minute budget per certificate per route; Table 2.8 shows the ladder. An em-dash marks a certificate whose run exceeded the budget; *o.o.m.* marks one that exhausted the machine’s memory first; *o.o.f.* (out of fragment) marks the scope boundary discussed below — the route declines any certificate outside its accepted fragment rather than guess at it, a refusal that costs completeness and never soundness — and kernel peaks for non-completing runs are reported as floors (the resident size when the run was cut).

| certificate                  | bytes   | proof nodes | compiled      | kernel        | kernel peak     |
|------------------------------|---------|-------------|---------------|---------------|-----------------|
| enclosure_v1_golden_cos6     | 603     | 1           | <i>o.o.f.</i> | <i>o.o.f.</i> |                 |
| ctmc_sis_gen                 | 919     | 3           | 2.4 ms        | <i>o.o.m.</i> | $\geq 124$ GiB  |
| ctmc_fk_mid                  | 1,793   | 35          | 51 ms         | <i>o.o.m.</i> | $\geq 124$ GiB  |
| micro2_stable                | 2,184   | 96          | 0.12 s        | —             | $\geq 0.75$ GiB |
| cartpole_core_decrease_s0001 | 4,068   | 65          | 0.43 s        | —             | $\geq 0.76$ GiB |
| rode_uniform_decrease        | 7,652   | 143         | 2.9 s         | —             | $\geq 0.76$ GiB |
| cartpole_dp_core_decrease    | 9,336   | 197         | 9.6 s         | n.a.          |                 |
| dp_composite_syzygy          | 17,591  | 377         | 99 s          | n.a.          |                 |
| dp_composite_eigenrate       | 22,056  | 647         | 7.4 min       | n.a.          |                 |
| lti_sampled_flow             | 24,686  | 1,693       | 8 min         | n.a.          |                 |
| acasx4_init_s0000            | 43,401  | 527         | —             | n.a.          |                 |
| dp_composite_smallgain       | 46,015  | 1,081       | —             | n.a.          |                 |
| acasx4_promise_closedloop    | 57,779  | 1,055       | —             | n.a.          |                 |
| rode_nest_shell              | 119,217 | 4,629       | —             | n.a.          |                 |
| rode_hold_flow               | 126,216 | 5,773       | —             | n.a.          |                 |

Table 2.8: The ladder. “compiled” is the median end-to-end wall clock of repeated passes of the compiled route; “kernel” is the wall clock of one kernel (*decide*) evaluation of the same bytes. Em-dashes are runs cut at the 10-minute budget; *n.a.* marks kernel runs not attempted because every in-fragment kernel attempt at smaller sizes had already ended cut or out of memory.

### 2.8.2 The scaling law

Across the 9 rungs the compiled route completes within budget, end-to-end time follows a power law in container bytes:  $t \propto B^{3.58}$  (95% CI [3.24, 3.92],  $r^2 = 0.989$  on log-log least squares). Container bytes is the best of the three natural size units as a regressor ( $r^2 = 0.989$ , against 0.962 for certificate rows and 0.909 for proof nodes) — expected, since the dominant cost is the reader: list-based CBOR decoding and seam assembly in a purely functional style, chosen so that the same definitions remain evaluable by the kernel. Nothing about the certificate format requires a superlinear reader, as the linear-time imported checkers on the same bytes demonstrate — and as the fast-path route’s own fitted exponent on this same ladder now measures (1.20, its confidence interval containing linear). Figure 2.1 shows the measured points, the fitted law, and the budget line — and, since the trichotomy’s claim is comparative, the same ladder through the toolkit’s other two checking routes, measured per certificate on the Arm host (section 2.8.6 carries the hardware and scope contract).

The kernel mode needs no fitted curve to make its point. Its smallest full acceptance during the route’s development — the 919-byte certificate, second rung of the ladder — cost 965 seconds and a 233 GiB peak on a 251 GiB development machine (the toolkit repository’s route documentation carries that receipt); the memory is the kernel’s reduction state, not the certificate. On this section’s 126 GiB reference machine the same certificate exhausts neither budget nor patience but memory, and every in-fragment kernel attempt

Figure 2.1: One ladder, three checking routes: the fast-path engine (geolog-alpha, blue squares, on the staged-chain sealed containers), the certified checker (qtslab, green diamonds, on the same certificates re-marked content-resolved — a container-table transform under which every certificate row is byte-identical), and the compiled Lean reflection route (red circles) with its fitted law. Blue and green medians are one process, end to end, pinned to one core of the Arm host; the red points are this section’s own protocol on its dedicated machine (the footnote of section 2.8.6 carries both). Open marks of either color sit *at* the dashed budget line: each true time lies above its mark. A rung with no mark on some route is a scope datum, not a failure — that route classes the certificate outside its accepted fragment and declines it (the caption of Table 2.8 and section 2.8.6’s footnote carry the per-route scope and hardware contract). The Lean fit uses only uncensored red points; where it crosses the budget —  $\approx 28$  KB of sealed container — is the admission threshold of Table 2.9. Each solid line is the same log-log fit to its route’s accepted medians: geolog-alpha at exponent 1.20 (95% CI [0.63, 1.78], containing linear;  $r^2 = 0.61$ ), qtslab at 3.10 ([2.30, 3.91],  $r^2 = 0.95$ ), Lean at 3.58 ([3.24, 3.92]) — one near-linear route and two superlinear ones, measured on the same certificates.

on the ladder ended cut at the budget, out of memory, or predictably unattempted (Table 2.8). The failure mode is content-dependent, not size-monotone: the 919-byte certificate took the whole machine's memory in under eight minutes, while certificates two to eight times its size ground past the budget inside a gigabyte — a  $\times 160$  spread in peak residency between neighboring rungs. What a given certificate makes the kernel's reduction state do is a property of its content (the working hypothesis is exact-rational arithmetic in kernel terms, untested here), not of its byte count. A certificate of under a kilobyte that the compiled route accepts in milliseconds is already past what the kernel evaluator will do inside a ten-minute, hundred-gigabyte envelope; that is the measured content of “too slow at machine scale,” stated with its numbers attached.

### 2.8.3 The fragment boundary

One ladder rung is not a timing datum but a scope datum: the smallest certificate (603 bytes, an interval-enclosure certificate whose obligations are discharged by *primitive applications*) is out of fragment for the route — the table's *o.o.f.* — and the route declines it: compiled and kernel agree, and the kernel's refusal is itself a theorem (decide proves the acceptance predicate false on those bytes). The same bytes are accepted by the reference checker, which settles the direction of the disagreement: the route's accepted fragment is the first-order pinned-vocabulary rule set, primitive applications lie outside it by design, and a checker asked about a certificate it cannot speak for declines it rather than guess. Every checker in this chapter draws some such boundary, always with the same sign — an out-of-fragment refusal costs completeness, never soundness; the certified checker classes this same rung outside *its* fragment too, naming the reason in its verdict (`fun_outside_fragment`), while the fast-path lane discharges it (Figure 2.1). Admission to the Lean route is therefore a conjunction: small enough, *and* inside the fragment. A species' first Lean attempt should be its smallest instance, which settles fragment membership in milliseconds before any batch of timings is scheduled.

### 2.8.4 The admission gate

Table 2.9 applies the fitted law to the certificate species of this chapter's campaigns: per species, the byte range of its committed certificates (container overhead added), the predicted compiled-route time at the median and maximum, and the verdict against the 10-minute budget. The table is the gate the re-run campaigns consume: a Lean-reflection timing column is attempted only for species that pass (or, at the runner's discretion, the passing fraction of a *partial* species), and the kernel mode is attempted for none — the measured points above place its envelope below every production species' floor.

### 2.8.5 The measurement before this one

This ladder is the route's second measurement, not its first. In July 2026, on the toolkit's predecessor binary certificate format (since retired), the same question was measured by the other road into the kernel — *elaboration*: an emitter translated certificate bytes into generated Lean source ( $\times 8$  expansion, byte-stable per-node templates across certificate kinds), and the elaborator produced kernel-checked object files (a further  $\times 24$ – $25$ ) closing with the same species of validity theorem. Three production certificates were taken to full kernel verdicts that way — 197, 377, and 1,081 proof nodes, at 3.4, 9–13, and 28 minutes of elaboration respectively, against 3–10 *seconds* for the certified checker build of the same era on identical certificate content and comparable hardware: a measured factor of  $\times 30$  to  $\times 250$  at kilobyte scale, growing with size. The same campaign took a streaming census of a real machine-scale certificate — a 43,285,639-node, 1.24 GB closed-loop neural-network verification certificate, semantically re-checked by a reference checker in 2.4 hours — and projected the elaboration route on it:  $\approx 7$  GB of generated Lean source,  $\approx 66$  million declarations in one namespace (about one hundred mathlibs),  $\approx 176$  GB of object files, and 1.4–2.7 core-years of serial elaboration, with memory the first wall. The numbers, the census, and the projection's stated assumptions are recorded in `lean-route/HISTORY.md`. That projection is why the present route abandons source generation altogether: a fixed decoder and checker are defined once, certificates arrive as ordinary input bytes, and the measured question becomes the reader's scaling law above rather than gigabyte-scale generated source.

| species                                                  | max B      | fragment | pred. med.     | pred. max      | verdict                |
|----------------------------------------------------------|------------|----------|----------------|----------------|------------------------|
| hardware liveness (circuits)                             | 2,627      | untested | 9.1 ms         | 0.22 s         | pass                   |
| Atari certified replay                                   | 5,113      | untested | 22 ms          | 1.9 s          | pass                   |
| FrozenLake 4x4 (det + slippery + sr34)                   | 52,015     | exp. in  | 15 s           | 97 min         | partial                |
| CliffWalking                                             | 71,872     | exp. in  | 14 min         | 5.1 h          | fail                   |
| FrozenLake 8x8                                           | 500,289    | exp. in  | 5.5 h          | 0.59 yr        | fail                   |
| Blackjack                                                | 115,779    | exp. in  | 10 h           | 28 h           | fail                   |
| Taxi (all weather/passenger variants)                    | 3,102,602  | exp. in  | 7 yr           | 400 yr         | fail                   |
| LunarLander / LunarLanderContinuous (statistical tier)   | 12,226,428 | untested | $\sim 10^4$ yr | $\sim 10^5$ yr | fail                   |
| published-table supermartingale corpus                   | 50,000     | exp. in  | 97 ms          | 84 min         | partial                |
| semiconductor fluid ladder (minifab)                     | 18,451     | untested | 65 s           | 2.5 min        | pass                   |
| semiconductor fluid ladder (mimac)                       | 401,455    | untested | 0.18 yr        | 0.27 yr        | fail                   |
| interval-enclosure certificates (primitive applications) | 603        | out      | 4.4 ms         | 4.4 ms         | <i>out of fragment</i> |

Table 2.9: The admission gate. Predictions apply the fitted law to each species’ certificate sizes in sealed-container bytes (census rows stated in committed-artifact bytes carry the measured container overhead as a declared correction); beyond the fitted range ( $\approx 25$  KB) they are extrapolations — one-sidedly corroborated by the budget-censored rungs up to 126 KB, order-of-magnitude statements past that. “Fragment” marks measured membership only for the ladder’s own species; *untested* species settle theirs with a one-instance probe before any batch attempt.

## 2.8.6 The route beside the other two

The trichotomy’s claim is comparative, so the honest summary is too.<sup>1</sup> On this chapter’s stored supermartingale corpus — 4,105 sealed containers, each one verification condition’s Bernstein Logic discharge at roughly one to fifty kilobytes — the certified checker’s current build replays every container at a pooled median of 30 ms, maximum 117 ms, on one Arm core (Table 2.3), and the fast-path engine’s sealed-container lane re-checks the whole corpus in wall-clock seconds (supermartingales/GLC-CERT.md). The compiled reflection route has not been batch-run on that corpus; the admission gate prices it (Table 2.9): verdict *partial*, with a predicted median near 0.1 s and a predicted maximum near 84 minutes, so only the passing fraction would ever be attempted. Figure 2.1 makes the comparison direct on the ladder itself, every route in its current build on identical certificate content: the fast path near-linear in bytes (exponent 1.20), the reflection reader at  $B^{3.58}$ , and the certified build accepting 7 rungs and cut at the budget on 7. Within the ladder the certified wall grows as  $B^{3.10}$  ( $r^2 = 0.95$ ) — statistically indistinguishable from the reflection reader’s exponent, while the fast path’s confidence interval excludes both — and across corpora content dominates bytes: the stored corpus above tops out at 117 ms per certificate at sizes where the ladder’s composite certificates cost minutes, which is how a 30 ms pooled median there and these walls here are both true. A species aiming certificates at the certified route should therefore run the same one-instance probe the admission gate prescribes for Lean: fragment membership and cost are both content-properties, settled cheaply on the smallest instance. The historical cross-check stands beside the figure: on the composite small-gain rung (1,081 proof nodes, 46 KB sealed), the certified checker of the elaboration era took about

<sup>1</sup> Hardware, per the conventions: the certified checker is timed on one core of an Arm host — the ISA its soundness theorem grounds in — with its own cross-machine spread measured under  $\times 1.15$ ; in Figure 2.1 the two production routes’ ladder points are one process per certificate, pinned to one performance core of one Arm box (Cortex-X925 + Cortex-A725), while the red points remain this section’s reflection timings (AMD EPYC 7B13, 16 threads, 126 GiB); the elaboration-era numbers are as recorded in lean-route/HISTORY.md. Every contrast quoted here is two or more orders of magnitude, and the measured cross-machine factor on the compiled route is a factor of a few — hardware choice cannot close any of them. Container forms, per route: the fast path consumes the staged-chain re-seals (lean-route/GLC-CERT.md), the certified checker the content-resolved mints (lean-route/tools/mint-qtslab-vintage.py states the container-table-only transform), and both carry the same certificate rows byte-for-byte as the committed fixtures the Lean route reads. Scope, shared by all three routes on this corpus: these certificates natively encode the Bernstein Logic fragment, which is the only fragment the certified checker consumes (theories/BernsteinLogic.geolog); the full QTSL theory is checked on the engine-side container lanes of section 2.9.

ten seconds on the same content in its own format's bytes (today's build, reading the unified sealed container, is cut at the budget on that rung), against past the ten-minute budget through the compiled reflection route and twenty-eight minutes through the retired elaboration route.

The conclusion the measurements support, stated as the front matter's expectation deserves: *confirmed, with its boundary measured*. For the kernel evaluator the confirmation is categorical — a certificate under a kilobyte already costs sixteen minutes and a quarter-terabyte of reduction state, and nothing larger completes at all — and for the compiled route it is a statement about scaling rather than about the route: below a few kilobytes the compiled reflection path is genuinely fast (the 919-byte rung's 2.4 ms is *under* the certified build's corpus median, on different certificates of the same format), but at  $\times B^{3.6}$  against the production checkers' linear-with-content growth, the ratio passes two orders of magnitude by fifty kilobytes and machine scale is out of reach by shape, not by constant factors. The route earns its keep on the other side of the ledger: full kernel verdicts on small certificates tie the certificate semantics to a proof kernel scrutinized by a community that owes this toolkit nothing — and the measured boundary is precisely why the certified binary, not the kernel, walks the forty-million-node instances.

**What is not claimed.** The law is a property of this route's current reader on one machine class, not of Lean, whose kernel and compiler are here being used far outside their engineered envelope on purpose; an index-structured reader would move the compiled curve substantially, and nothing in the trichotomy's argument depends on it not moving. Cross-machine transfer of the constants is measured to be worth a factor of a few (the 2,184-byte rung runs 27.6 ms on the development machine cited above and  $\approx 120$  ms here); the exponent, not the coefficient, is the portable content. Species predictions inherit a byte-basis caveat until each campaign banks per-instance container sizes, and the admission table regenerates from those receipts by the same make target that produced it. The elaboration-era numbers of `lean-route/HISTORY.md` are development-record measurements on a retired format, quoted for the route's history with their measured/projected distinctions preserved; they are not re-derivable from this repository, and no other number in this chapter rests on them. Finally, the ladder's timings were taken against the committed fixtures; the same certificate content re-sealed on the unified certificate schema is already committed beside them (`lean-route/out/glc-baked/`, with the content-identity argument stated in `lean-route/GLC-CERT.md`), and when the ladder re-runs on those containers this section's numbers move with them, per the reproduction discipline of section 2.9.

## 2.9 Reproduction

Every campaign in this chapter ships its evidence in the coalition's experiments repository (`maitria-coalition/qtsl-experiments`): the certificates themselves, committed byte-for-byte; their mutant batteries; the machine-readable receipts (JSON) from which this chapter's tables are re-derived mechanically; and the independent checkers, imported from the `qtsl` repository at pinned revisions. One make target per family re-verifies the stored certificates and mutants through the checkers and regenerates the tables.

The certificate vocabulary itself is committed, as data: the `qtsl` repository ships the theory pair `theories/BernsteinLogic.geolog` — the Bernstein Logic proof tower, exactly the fragment the certified checker consumes — and `theories/Qtsl.geolog` — the omnibus theory extending it with systems, specifications, and the judgments connecting them — and a certificate is ordinary rows of these theories; there is no bespoke certificate file format. That unified schema is the standing discipline for everything this chapter reports: one certificate vocabulary for every campaign, revision-pinned modelling-toolkit producers used where each family has shipped producer coverage, the database engine as the fast-path checker, and an extraction tool reducing a full-QTSL certificate to its Bernstein Logic obligations for the certified checker. Families without a distributed producer retain a revision, invocation, and binary-digest provenance record rather than being described as runnable from a public clone. The shipped form is the sealed container — one signed `geolog` commit per certificate, re-verified from the bytes alone, with obligation and claim counts demanded exactly: deleting a proof node leaves every surviving obligation true, so the count gate is load-bearing, and a container that claims nothing is refused rather than vacuously accepted.

The campaigns of this chapter predate that unification, and the transition is in flight, not finished. Certificates produced on the earlier staged vocabularies remain the evidence behind the tables: they stand as the record of the campaign that produced them, still re-checked by the make targets, and nothing in them is presented

un-checked. Re-emissions on the unified schema have landed for the first families — the fluid-drift, published-table-sweep, Lean-ladder, and Gymnasium lanes, with the SPDE family's noise spectra re-homed first under its split-container design; each re-emission's content deltas are disclosed per container in its family's manifest. The uniform re-conduct of every campaign through its revision-pinned producer is the successor work the tables track: as family-scoped producer coverage and re-conducted receipts land, the numbers re-derive from them, and the superseded certificates retire to an archive rather than being silently rewritten.

A producer is never part of any trust story, so the audit path is the same on either side of the transition: read a checker, run it against the shipped certificates and their mutants, and only then decide what the tables mean. The published-table sweep's certificates are additionally stored as plain-text listings of database object rows — the geolog encoding, human- and checker-readable alike — each pinned by hash in a manifest, and its containers prove content identity against those listings at production, so the certificate a checker reads is the certificate a reviewer can read. Per the preview note at the front of this volume, artefacts migrate to the public repositories as they graduate; until a cited artefact appears there, treat its mention as a statement of what exists, not yet a link.

PART I

# Geolog

---

## Quick Start

---

In this chapter you will install `geolog`, write a theory and a handful of facts in one file, and run the chase: the engine will derive the tables your axioms entail, invent nothing you did not license, and report — rather than repair or reject — the one state your theory forbids. At the end you will look at the theory you wrote and find it is itself rows. The whole path fits in one sitting; every command is copy-pasteable, and every output shown is the verbatim transcript of a real run.<sup>1</sup>

### 3.1 Install

A Rust toolchain is the only prerequisite (stable channel; `rust-toolchain.toml` pins the components).

```
git clone https://github.com/maitria-coalition/geolog-alpha
cd geolog-alpha
cargo install --path crates/geolog
```

A fresh clone compiled in about a minute on the commodity arm64 box that regenerates this book's transcripts. `geolog --help` lists ten verbs; the three this chapter uses are `check`, `chase`, and `rows`.

### 3.2 A theory

The example is a freight network, small enough to hold in your head: places, direct hops, and reachability. The file `examples/routes.geolog` declares one sort, two relations, and three axioms:

```
theory Routes {

  Node : Set;

  // Asserted: a direct hop exists.
  Edge : [src: Node, tgt: Node] -> Prop;

  // Derived: some chain of hops exists. Rows appear exactly when the
  // axioms force them – never asserted directly.
  Path : [src: Node, tgt: Node] -> Prop;

  // `chase` marks a derivation rule: the axiom FIRES, creating rows.
  // (`report` marks a constraint: violations are judged, nothing is
  // created; an unmarked axiom defaults to report – the least-
  // dangerous reading, so derivation is always an explicit choice.)
  chase ax/path/edge : forall a : Node, b : Node.
    [src: a, tgt: b] Edge |- [src: a, tgt: b] Path;

  chase ax/path/trans : forall a : Node, b : Node, c : Node.
    [src: a, tgt: b] Path, [src: b, tgt: c] Edge
    |- [src: a, tgt: c] Path;

  // A denial: this network is required loop-free. A commit that lands
  // a cycle is not rejected – the violated denial is REPORTED as a
  // judgement, and repair is a further ordinary commit.
```

<sup>1</sup>The book's build regenerates these transcripts by executing the printed commands against the committed examples, and each fragment's header records the exact tool revision it ran against (all runs on one commodity arm64 box).

```

    report ax/no/loop : forall a : Node.
      [src: a, tgt: a] Path |- false;
  }

```

Four things to read off the shape.

1. Relations are declared over named record fields, and axioms are *sequents*: universally quantified entailments, each premise a conjunction of atoms, each conclusion here a single atom. The odd one out is the third axiom, whose conclusion `false` makes it a *denial*: a state the theory forbids.
2. The word in front of each axiom's name is its *mode mark*, and the file's own comments state the semantics: `chase` fires, `report` judges, and an unmarked axiom means `report`. An axiom creates rows only where its author said so in as many words.
3. Note what the mark does *not* do: nothing in the *declarations* marks `Path` as derived. The mode belongs to the axiom, and `Path` being a table nobody writes remains an emergent fact — about which relations your chase-marked axioms conclude into and which your commits assert into — not a schema annotation.
4. The slash in `ax/path/edge` is nothing special: slash-names are ordinary identifiers, used by convention for namespacing. The `ax/` prefix, however, does real grammatical work: it makes a statement an axiom rather than a declaration, so a sequent written under a name like `my/rule` is a syntax error. The Reference Manual (chapter 5) spells out these name rules.

Nothing travels beside the theory: a `.geolog` file is self-contained — everything it draws on is either declared in it or imported at the top. This is the *roster-totality* discipline: every declared relation has a decided evaluator. ordinary (asserted or chase-derived) is the default, declared by writing nothing. When a relation is instead decided by a bounded external procedure, an import line says so — `import <provider>.{rel}`; — classifying it as a *side-condition* awaiting that provider. The same import syntax authorizes builtin ground vocabulary by name (`import std.{Q, q_lt}`;). Nothing guesses on your behalf: an `import std` line naming something outside the builtin roster refuses at once, listing the importable names. This chapter's example needs no imports; every relation in it is ordinary, and the file's opening comment says so.

### 3.3 An instance

The same file carries the facts, in an instance block — element declarations first, then facts in the same record idiom the axioms use:

```

instance Demo : Routes {
  hub, east, west, port : Node;

  [src: hub,  tgt: east] Edge;
  [src: hub,  tgt: west] Edge;
  [src: east, tgt: port] Edge;
}

```

Elements are declared before use; a fact naming an undeclared element is an error, never a silently minted row. (`geolog check` validates all of this — declarations, field sets, sorts — without running anything.)

The map is worth ten seconds: `hub` ships to `east` and to `west`, and `east` ships on to `port`. Before running anything, guess which pairs the axioms will put in `Path`.

### 3.4 The chase

```

$ geolog chase examples/routes.geolog
sorts:
  Node — 4 elements (4 seeded)
relations:
  Edge — 3 rows (3 seeded, 0 derived)
    [src: east, tgt: port] Edge

```

```

    [src: hub, tgt: east] Edge
    [src: hub, tgt: west] Edge
    Path – 4 rows (0 seeded, 4 derived)
    + [src: east, tgt: port] Path
    + [src: hub, tgt: east] Path
    + [src: hub, tgt: port] Path
    + [src: hub, tgt: west] Path
    fixpoint: reached, no judgements – the model is saturated.
    $ echo $?
    0

```

Look at the + rows: tables nobody wrote. [src: hub, tgt: port] is in Path because ax/path/trans forces it from two rows you did write, and the chase ran that forcing to its *least fixpoint* — everything the axioms entail, nothing they do not. (The other three are your own hops, lifted into Path by ax/path/edge: one new reachability fact, four new rows.) “Derived” names provenance rather than any lesser grade of truth: these rows are as queryable as the seeded ones, and rerunning from the same facts re-derives exactly the same table.

### 3.5 Break it

Add one hop to the instance block — the return leg that closes a loop — and save the edited file as routes-cycle.geolog:

```

    [src: port, tgt: hub] Edge;

    $ geolog chase routes-cycle.geolog
    sorts:
      Node – 4 elements (4 seeded)
    relations:
      Edge – 4 rows (4 seeded, 0 derived)
      :
      Path – 12 rows (0 seeded, 12 derived)
      :
    judgements (3):
      denial violated: ax/no/loop at [a: hub]
      denial violated: ax/no/loop at [a: east]
      denial violated: ax/no/loop at [a: port]
    $ echo $?
    1

```

Read what did *not* happen. The write was not rejected: the facts landed, and the chase saturated over them (twelve Path rows now: each of the three places on the loop reaches all four, itself included). The violation was not repaired: no engine deleted your hop or picked a row to sacrifice. What happened is a *judgment* — the very thing ax/no/loop’s report mark asks for: the violated denial is reported, with the axiom’s own name and the binding that witnesses it, and the exit code says so. Three judgments here, not one: the same loop, witnessed once from each place standing on it. If you have operated an event-sourced system, this is a familiar posture done formally: an append-only log can land in a state some invariant marks invalid, and the repair is a further ordinary commit — made by whoever owns the workflow, not by the database guessing. The Tutorial (chapter 4) makes this the centre of the story.

### 3.6 The theory is rows

One last look before you go:

```

    $ geolog rows examples/routes.geolog
    // Declaration rows in the GeologMeta idiom (the schema you wrote is
    // itself data). refs: L<n> = local element minted at op[n]; G<name> =
    // genesis identity. This is the declaration slice; axioms are rows
    // too, in the same substrate – the committed listings under
    // theories/generated/ carry complete worked examples.

```

```

op[ 0] elta sort=G<Theory>                // Theory "Routes"
op[ 1] elta sort=G<Sort>                  // Sort "Node"
op[ 2] funa fun=G<Sort/name> args=[L1] value=str:"Node"
op[ 3] funa fun=G<Sort/theory> args=[L1] value=L0
op[ 4] elta sort=G<Fun>                   // Fun "Edge"
op[ 5] funa fun=G<Fun/name> args=[L4] value=str:"Edge"
:
op[ 8] elta sort=G<Field>                 // Field "src" of Edge
op[ 9] funa fun=G<Field/fun> args=[L8] value=L4
:

```

The theory you wrote in §3.2 is itself data: a Theory element, a Sort element with a name row and a home row, Fun and Field elements for each relation and its columns — rows in the *meta-schema*, the schema language that is itself a geolog theory. As the listing's own header says, this is the declaration slice; axioms continue as rows in the same idiom, and the repository's `theories/generated/` directory carries complete committed listings — the full Petri-net theory runs to 1,239 ops. Schemas, extensions, and migrations live in the same substrate they govern, so you can version them, diff them, and derive facts about them just as you would any other rows.

### 3.7 Where to next

The Tutorial (chapter 4) works an event-sourced order flow with two writers: views only the merged logs can derive, two replicas' records identified by congruence rather than a conflict resolver, a witness the chase invents under an existential axiom, a violation that only the merge surfaces, and the signed commit log underneath, which can say things a broker cannot. The Reference Manual (chapter 5) gives the systematic account. The part closes with diagrams as data (chapter 6): one incidence genus, stored and checked as rows, for every diagram the wider toolkit traffics in. And for the road from a model to a checked temporal claim about it — the reason this database exists in this book — start the QTSL part at chapter 7.

# Tutorial

---

DRAFT

If you have operated an event-sourced system, you have already run most of geolog’s architecture on convention [139]. An append-only log serves as the source of truth. Derived views are rebuilt by replay. New capability arrives as new producers and consumers, never as mutation of shared state. And everybody promises not to write to the derived tables by hand. Kafka gives you the log, Flink or Feldera maintains the views, a schema registry polices the shapes, and the promises live in code review.

geolog takes that architecture and makes the promises structural. No fold code that somebody wrote and everyone else must believe maintains the derived views; the declared axioms *entail* them instead, and they can be recomputed and checked from the log alone. The chapter’s spine is one example, an order flow with two writers: views no single writer can derive (§4.1–4.2), merge as set union plus re-derivation (§4.3), the signed commit log and what it can say that a broker cannot (§4.4), schemas as data (§4.5), and the ground vocabulary (§4.6). A worked example imported from an independent project follows: the core theory of a proof assistant, expressed whole, together with instructions for converting its native data in both directions (§4.7). A plain-dealing scorecard against the SQL stack you already run (§4.8) and the handoff to temporal claims (§4.9) close the chapter. Every transcript is verbatim from a real run against the geolog-alpha repository (the order flow against `examples/orders.geolog` and the single-diagram crossing of §4.7, last re-executed 2026-07-30 against the import-era tree; the corpus-scale measurements behind §4.7 executed 2026-07-27); the receipts sit at this chapter’s source tail.

## 4.1 Views you do not maintain

Here is the domain, whole. Two writers will keep logs against it: a storefront (payments, cancellations) and a warehouse (allocations, shipping records).

```
theory Orders {

  Order      : Set;
  Shipment   : Set;

  // Events -- asserted rows, the writers' ground truth.
  Placed     : [o: Order] -> Prop;
  Paid       : [o: Order] -> Prop;
  Allocated  : [o: Order] -> Prop;
  Cancelled  : [o: Order] -> Prop;

  // Views -- derived rows, never asserted by a writer...
  Shippable  : [o: Order] -> Prop;

  // ...except ShippedVia, which writers MAY also assert (a recorded
  // manifest); where no record exists, the chase invents the witness.
  ShippedVia : [o: Order, s: Shipment] -> Prop;

  chase ax/ship/ready : forall o : Order.
    [o: o] Paid, [o: o] Allocated |- [o: o] Shippable;

  chase ax/ship/manifest : forall o : Order.
    [o: o] Shippable |- exists s : Shipment. [o: o, s: s] ShippedVia;
```

```

    chase ax/manifest/unique : forall o : Order, s1 : Shipment, s2 : Shipment.
      [o: o, s: s1] ShippedVia, [o: o, s: s2] ShippedVia |- s1 = s2;

    report ax/no/zombie : forall o : Order, s : Shipment.
      [o: o] Cancelled, [o: o, s: s] ShippedVia |- false;
  }

```

Read ax/ship/ready the way you would read a view definition, because that is what it is:

```

CREATE MATERIALIZED VIEW shippable AS
  SELECT o FROM paid INTERSECT SELECT o FROM allocated;

```

The chase mark plays the role of CREATE here. It opts the sequent into *firing*, which is to say into deriving rows. A report mark, or no mark at all (unmarked means report), would instead make the same sequent a checked constraint, judged and never fired. The join stays identical; what changes is who owes whom what. A materialized view comes out of the query you wrote together with the engine's maintenance code, and it contains whatever that code computed. A geolog view, by contrast, is a logical consequence. The chase computes the *least fixpoint* of the axioms over the asserted rows: every row the axioms force, and no row they do not. Anything that can replay the log and read the theory can then re-derive and audit every row, with its provenance. In the SQL world the nearest neighbours are Feldera and the DBSP line of work [31], and the kinship is genuine: declarative view definitions, incremental maintenance with a correctness story, replay from a log. What differs is the view language itself. A SQL view computes what its query says; a geolog view is an entailment in geometric logic [127, Part D1], the fragment of first-order logic whose sequents have a conjunction of atoms as premise and a disjunction of existentially quantified conjunctions as conclusion. That fragment is why the other three axioms above (an existential, an equality, and a denial) are ordinary view definitions here, while over there they are not expressible as views at all. Those three carry the rest of this chapter.

Two caveats, up front. The first is maintenance. Feldera's engine is incremental to its bones, and at production scale that maturity is real (§4.8). In this preview, geolog's chase evaluation is a deliberately naive reference implementation, differentially tested against an independent engine and built to be right rather than fast; incremental maintenance ships today only for its violation views, where the failing set is kept current under row deltas and never recomputed from scratch. The second is expressiveness, and it cuts the other way. Aggregates such as SUM and windowed rates, the bread of streaming SQL, are not native vocabulary in the geometric fragment. Counting enters through explicit constructions or through the ground seam (§4.6), and where your computation is aggregate-shaped, today the SQL stack simply wins.

## 4.2 One writer at a time

The two writers' logs live as two instance blocks in the same file; in the durable pipeline each would instead be a stream of signed commits (§4.4). The storefront saw payments and a cancellation, and it holds the carrier's tracking record for order o1. The warehouse allocated stock for both orders, the cancellation not having reached it, and it holds its own record of the same shipment, the printed label:

```

instance Storefront : Orders {
  o1, o2 : Order;
  sf_record : Shipment;

  [o: o1] Placed;  [o: o1] Paid;
  [o: o2] Placed;  [o: o2] Paid;
  [o: o2] Cancelled;

  [o: o1, s: sf_record] ShippedVia;
}

instance Warehouse : Orders {
  o1, o2 : Order;
  wh_label : Shipment;

  [o: o1] Allocated;
}

```

```

    [o: o2] Allocated;

    [o: o1, s: wh_label] ShippedVia;
  }

```

Chase each log alone (`--instance` selects blocks):

```

$ geolog chase examples/orders.geolog --instance Storefront
:
Shippable - 0 rows (0 seeded, 0 derived)
ShippedVia - 1 row (1 seeded, 0 derived)
  [o: o1, s: sf_record] ShippedVia
fixpoint: reached, no judgements - the model is saturated.
$ echo $?
0

```

The warehouse's run is symmetric: no Paid rows, so again no Shippable, and exit 0. Notice what clean means here. *Each writer's log is locally consistent*. The storefront knows o2 is cancelled but sees no shipment for it, and the warehouse sees no cancellation at all. Every partial view is innocent. If the two logs were Kafka partitions consumed by separate services, each service would be reporting green.

### 4.3 Merge is set union plus re-derivation

Now merge. Merging replicas in geolog takes no protocol. The commit bag is a set, union is union, and the chase re-derives. Run without `--instance` and the file's blocks seed as their union. Element names shared across blocks denote the same element, the CLI's small-scale stand-in for the content-addressed identity of §4.4:

```

$ geolog chase examples/orders.geolog
sorts:
  Order - 2 elements (2 seeded)
  Shipment - 2 elements (2 seeded, 1 invented by the chase,
                      1 merged by congruence)
  merged: sf_record = wh_label
relations:
  :
  Shippable - 2 rows (0 seeded, 2 derived)
  + [o: o1] Shippable
  + [o: o2] Shippable
  ShippedVia - 2 rows (1 seeded, 1 derived)
    [o: o1, s: sf_record=wh_label] ShippedVia
  + [o: o2, s: ?Shipment.0] ShippedVia
judgements (1):
  denial violated: ax/no/zombie at [o: o2, s: ?Shipment.0]
$ echo $?
1

```

Four things happened, and they are four fifths of this database's distinctive behaviour, so take them one at a time.

**The union derived what neither log could.** Shippable was empty in both single-writer runs, and the merged run derives it for both orders, because `ax/ship/ready`'s premise spans the two logs. That much is the ordinary magic of any log-merging system; a Felter pipeline consuming both topics would derive the same join. What it did not require was a pipeline topology. The axiom was already the join, and *any* subset of commits chases to its own well-defined fixpoint.

**The two writers' records became one shipment.** The storefront's `sf_record` and the warehouse's `wh_label` are two elements naming, as it turns out, one real shipment. `ax/manifest/unique` says as much: a shipment is one shipment. The engine's congruence closure *identifies* the two elements, and the report prints the merged element as `sf_record=wh_label`. Contrast the CRDT discipline you may run on Kafka-adjacent state stores. There, convergence is bought by designing every value as a lattice and every merge

as a join, per type, by hand, in advance. Here identity is a *logical* matter, decided by the theory's equality axioms and computed by congruence, and it composes with everything else the axioms say. It is also a mode *choice*, made where the axiom is written. `ax/manifest/unique` is chase-marked deliberately, because identification is this axiom's job; report-marked, the same sequent would instead judge two distinct records as a violation, which is the right reading in a domain where identity is content and merging would invent facts. (When two elements merge, everything known about either transfers to the one survivor. Judging `ax/no/zombie` against the invented witness below already relies on that.)

**The chase invented a witness.** Order `o2` became Shippable, and `ax/ship/manifest` demands that a shipment exist for every shippable order. No writer recorded one, so the chase minted `?Shipment.0`, a fresh element about which nothing is known except what the axiom forces. This is the *restricted chase*: existentials invent a witness only where no witness already exists (order `o1`, which had records, got no invention). If you know database theory you recognize tuple-generating dependencies and the chase from the classical literature [62, 72]; if you know event-sourced systems, read it as the database itself filing the missing follow-up event, typed, provenance-tracked, and only when entailed.

**The violation surfaced only at the merge, and was reported rather than resolved.** Both logs were locally clean. Their union contains a cancelled order with a shipment, and `ax/no/zombie` forbids precisely that. The chase does not reject the merge, since there is nothing to reject; the union of two sets of commits is a set of commits. Nor does it pick a loser or roll anything back. It reports the judgment, with the axiom's name and the witnessing binding, and exits nonzero. That posture is the event-sourcing one, held formally: *invalid states are representable, detected, and repaired by further ordinary commits* — a compensating cancellation of the shipment, a voiding of the cancellation, whichever the workflow's owner chooses. What the database contributes is that “invalid” is a theorem rather than a code path someone remembered to write, and that the judgment itself is data an agent can act on. (Where an axiom's conclusion offers a genuine *choice* of repairs, a disjunctive head, the engine likewise picks nothing, and the judgment carries the menu. The engine calls these branch points; this example's judgments are denials, menus of length zero.)

If you have fought a Kafka consumer-group rebalance that replayed a partition into a half-updated store, or reconciled two services' databases after a network partition, this section is the pitch. Merge here is set union, and so it is *always* defined, order-free, and idempotent; and every consequence of the merged log, including its violations, can be re-derived by anyone from the log alone.

## 4.4 The log is the ground truth

Everything so far ran from a source file, because this is a tutorial. In geolog, “the facts” take durable form as a log of *commits*: content-addressed, ed25519-signed envelopes whose payloads carry just the kind of rows you have been reading, and whose causal dependencies are part of the signed content. Crossing from the file to that log is one verb:

```
$ geolog seal examples/orders.geolog --store orders-store --repro
repro-signed (public seed "geolog-seal-repro-v1" – reproducibility, not authority)
sealed examples/orders.geolog: 1 theory, 4 axioms, 197 revision ops
revision commit: b128db74d04f92bb0fdc5aec5a26f1d67b5504ba9289a7e888b487c1ee232aa4
C1 revision hash: c7de71b56edc728bc65daba559d3e3f1b0bf32bf2030689de4e1b69d64066f7f
seal commit:      e69f4611e367e91c8509731fc04f349ccf0b18beef0ealf87788ce6351505a59
store: genesis minted, comparisons minted, revision minted, seal minted
```

The theory's declarations compile to meta-schema rows (§4.5), the rows seal into a signed revision commit, and the store on disk now holds the envelope shapes the storage crates document and test (`geolog-envelope`, `geolog-store`, and `geolog-sync`, each with its differential partner named in its README). Sealing is deterministic: re-running the command reports every commit already present, and `--repro` signs with a public seed so that the hashes above reproduce from a fresh clone (reproducibility, as the tool says, not authority). `geolog check --store` and `geolog chase --store` then run the strata you already know over the sealed source instead of the file, after signature verification and a coherence gate; the reference manual's CLI section (§5.14) walks the whole verb family, `extract` and `load` included.

The architecture invites a comparison. A Kafka topic with infinite retention is also an append-only ground truth, and replay-rebuilt views are also disposable. Three differences are worth having words for.

**The log forms a set rather than a sequence.** A topic is an ordered sequence per partition, and that order carries real weight: consumers coordinate offsets, rebalances are delicate, cross-partition order is undefined. A geolog commit bag is unordered. Causality is explicit, since each commit names its dependencies by hash, and derived state does not depend on admission order. The repository’s battery includes a rebuild invariant that diffs incrementally-maintained state against a from-scratch replay, and a divergence is a release-blocking bug. “Replays in any order to the same fixpoint” is the property that made §4.3’s merge a non-event.

**Writers are cryptographic identities, and equivocation is detectable.** A broker will happily append whatever a producer sends, and if a compromised or buggy writer tells two consumers two different stories, nothing in the topic model even states the offence. geolog commits are signed and content-addressed, and a writer’s log is a hash-linked chain. A writer that forks its own history, which is to say equivocates, is detected *structurally* at sync time, from the bytes alone, with no consensus protocol and no quorum; the same mechanism makes CRDTs Byzantine fault tolerant in Kleppmann’s construction [138]. (The repository’s envelope crate ships the demonstration as a test: two signed commits claiming the same chain position are the offence, exhibited and caught.)

**Validity is per-commit and logical.** Because consequences and violations re-derive from any subset of the log, “which commits does this judgment implicate” is a well-posed question. The provenance machinery exists in the engine, so that every derived row and every invented element carries its firing history; and the engine’s validity layer (geolog-chase/validity in the repository) makes the per-commit verdict itself durable: it replays a commit’s inclusive causal closure into a content-addressed snapshot and folds one verdict per commit — clean, judged with its violations attached, or a named abstention (pending, unsupported, indeterminate), never a silent skip — with rebuild-order and cross-process determinism tested down to byte-identical snapshot bytes, so two replicas that judge the same commit publish the same judgment. Its first version replays a deliberately narrow fragment (one theory revision per closure, unmarked axioms only), and the tutorial CLI does not surface the pipeline yet. Capability-scoped authorization over the same substrate, meaning who may extend which theory and assert into which relation, is likewise arriving as an algebra over commits rather than as an ACL bolted on beside them (geolog-caps ships the algebra today; enforcement at the store boundary is design tense).

And the repository eats its own cooking: its committed theory goldens are themselves stored as signed artefacts, minted by a public, documented ceremony, and

```
| cargo run -q -p geolog-ceremony -- verify --root theories
```

re-derives them byte-identically from their committed listings and verifies the committed signatures, the golden-drift alarm that runs in every CI pass.

## 4.5 Schema is data

The Quick Start ended with geolog rows. The theory you write is itself rows: Theory, Sort, Fun, and Field elements in the *meta-schema*, the schema language that is a geolog theory like any other. In an event-sourced shop this should land as the resolution of a familiar irritation, the schema registry. Avro or protobuf schemas live *beside* the topics, in a registry with its own evolution rules (backward, forward, or full compatibility), its own versioning, and its own failure modes: a second database whose consistency with the first is everyone’s job and no one’s.

In geolog there is no second database. A theory arrives as a *revision*, a sealed batch of meta-schema rows, committed, signed, and content-addressed just like every other commit, with its dependencies named. Extending a schema means a further revision that depends on the first. Two independent extensions merge like any other commits, by set union, with the chase over the meta-schema re-deriving the combined signature. And “what did the schema look like when this row landed” is a query over the same log as the row. Annotations follow the same pattern instead of a special mechanism: the repository’s worked

units-of-measure theory decorates an existing theory's declarations with dimension gradings from the *outside*, as ordinary relation rows over Fun and Sort elements, without touching the annotated theory's bytes.

Here is what ships today in the alpha repository: the meta-schema itself, the genesis golden of §4.4's ceremony; the reference row listings and their generators for the worked theories under theories/; the theory-to-rows compiler and the sealed-revision conformance loader, with byte-identical round-trips on the committed corpora and loud rejections collected per rule; and the revision-level machinery, namely declaration indexes, signature hashes, and a programmatic revision-body builder. The `geolog` rows verb you ran is a faithful *view* of the declaration slice, and `geolog seal` runs the same compilation for keeps: the transcript of §4.4 sealed the order theory as a signed revision of 197 meta-schema operations. Cross-revision extends, parameterized theories, and instances as first-class elements are specified in the ruled design documents and arrive as that store grows; the tutorial's single-file extends, which the CLI does accept, is the in-file shadow of that mechanism.

## 4.6 Ground vocabulary: decided, not stored

Everything so far has been finite rows over declared sorts. Real domains want numbers, timestamps, and comparisons, vocabulary whose extension no log could store (*every* pair of rationals with  $a \leq b$ ?) and no chase should enumerate. `geolog`'s answer is the *ground seam*. Relations and functions over immutable carriers are declared as theory rows like everything else, but *decided* by registered procedures: exact arbitrary-precision rational arithmetic, and calendar arithmetic whose semantics are documented and tested against PostgreSQL's (`date + interval` behaviour, chosen precisely so a SQL practitioner's instincts transfer and the corner cases are somebody's published corner cases rather than ours).

Two disciplines make the seam trustworthy rather than a trapdoor. The first is *refusal over guessing*. Ground vocabulary an application declares but no provider implements does not default, approximate, or silently empty; a plan that cites it cannot even be expressed, and the refusal names the atom. (A division's graph simply contains no row for a zero divisor, so "divide by zero" is underivability rather than an exception.) The second is *the lane law*: an accelerated implementation may change *cost*, never *verdicts*. Every fast lane is conformance-gated against the always-on exact reference, and a lane that cannot pass its battery does not dispatch. If your mental model of database extension points is user-defined functions, hold on to this contrast: a UDF is trusted code in the query path, whereas a ground provider is an untrusted proposal bound to a declared signature, adjudicated by the engine, with an exact reference underneath it.

(The tutorial's CLI bridge does not yet reach the ground seam. `geolog chase` today covers declared sorts and Prop-valued relations, and it says so loudly when a theory wants more. The engine-level seam, the exact-rational floor, and the calendar corpus are in the repository under test; the worked Petri-net theory shows the discipline of doing real arithmetic *without* the seam, as chase-derived rows over an explicit number ladder.)

## 4.7 Worked example: alifib in geolog

Everything in this chapter so far was designed to teach this chapter. This section imports a structure that was not. *alifib* [105] is an experimental programming language and interactive proof assistant founded on higher-dimensional rewriting, developed by Amar Hadzihasanovic together with Alex Kavvos within ARIA's Safeguarded AI programme; its mathematics is Hadzihasanovic's theory of directed complexes and molecules [104], and its data structures grew out of joint work with Diana Kessler [106]. In *alifib* a type is a directed cell complex; a value is a *diagram* drawn in that complex; and a computation on  $n$ -dimensional data is itself a diagram, one dimension up. Running a program builds a witness of the whole computation, a higher-dimensional term you can inspect, paste into larger diagrams, and reason about; the project calls the property *computational transparency*. Rewrite rules are ordinary generators one dimension up, so there is no separate sort of rules anywhere in the language, and an execution trace is a term like any other.

Two of this chapter's themes meet in it, and it forces a third; that is why it earns a section. First, schema as data (§4.5) at full stretch: the whole proof theory lands as one ordinary `geolog` theory, seven sorts, thirty-eight functions and relations, twenty-four axioms, with no extension to the meta-schema at all.

Second, decided rather than stored (§4.6): every judgment the alifib engine computes over its finite combinatorial data — whether a paste is legal, whether a boundary pair is round, whether an incidence table matches a realized shape — enters the theory as a side-condition relation whose evaluator is the engine itself, the ground-seam discipline pointed at a full external prover rather than at rational arithmetic. Third, the forced one: the geometric fragment offers no negation in premises, and a theory of cell complexes keeps wanting one sentence of that shape (“this cell has no coface”). The stored-complement idiom below carries that sentence without leaving the fragment.

The theory ships as `theories/Alifib.geolog` in the `geolog-alpha` repository, and its opening `import` header is the decided-versus-stored split of §4.6 written down: the file imports its eight engine-decided judgments from the `alifib` namespace (each import classifying that relation `side-condition` — decided by a bounded external procedure), and every relation it declares without importing is ordinary, the default. The check verb runs green on it:

```
$ geolog check theories/Alifib.geolog
[1/5] parse + normalize + lint: theories/Alifib.geolog @ 2e60dd6 (452 lines)
      1 theories; 24 axioms (0 moves; aux helpers: none)
[2/5] geometric linter: CLEAN
      :
[5/5] instance conformance: no instance blocks in this file
modes: 6 chase · 18 report (18 by the unmarked default) · 0 refuse
      :
CHECK: GREEN
$ echo $?
0
```

The excerpts below are the teaching spine, roughly a third of the theory; the axioms not shown (execution traces as first-class terms; roundness of each generator’s boundary pair, the shape condition on a single cell; the remaining three sequents of the boundary-parity family; uniqueness of a cell’s coordinate; homing of boundary rows and map images) repeat the three patterns you are about to see. The theory splits into two tiers, the syntax of assemblies and the incidence data of the shapes they realize, and the walk takes them in order. One caveat before it starts: the tutorial CLI’s `rows` and `chase` verbs do not reach this theory yet — its element-valued function symbols are engine IR the current chase bridge does not carry — and both refuse loudly, each naming its workaround in the refusal. The transcripts here therefore ride `check`, `census`, and the conversion tools, and the excerpts themselves are kept faithful by construction: concatenated in source order they form a well-formed theory that `geolog check` accepts (the receipt at this chapter’s source tail records that run).

#### 4.7.1 Paste trees as constructor rows

```
theory Alifib {

  AType : Set;    // a type: a directed complex, elaborated
  Gen   : Set;    // one generator (cell) of a type; a rewrite
                        // rule is a Gen one dimension up
  Diag  : Set;    // a diagram AS ASSEMBLY -- a binary paste tree
  AMap  : Set;    // a map between types (generator-to-diagram images)
  Cplx  : Set;    // a materialized oriented graded poset
  Cell  : Set;    // one cell of a Cplx
  // (the seventh sort, Trace, records executions: a witness diagram
  // one dimension up, with its endpoints)

  Gen/type : Gen -> AType;
  Gen/dim  : Gen -> Nat;
  Gen/src  : Gen -> Diag;  // PARTIAL: absent iff dim = 0 --
  Gen/tgt  : Gen -> Diag;  // a 0-cell has no boundaries

  dGen    : [g: Gen] -> Diag;                // a single cell
  dPaste  : [k: Nat, l: Diag, r: Diag] -> Diag; // l #k r
```

`alifib` builds diagrams by *pastings*:  $l \#_k r$  glues two diagrams along their shared  $k$ -dimensional boundary,

and the engine stores a diagram as its assembly history, a binary tree of pastes over single-cell leaves. The two constructors above mirror that representation without loss. Because `dPaste` is a function — one value per argument tuple, an equality the chase maintains by merging — two occurrences of the same tree denote one `Diag` element, and structurally equal assemblies are shared: the engine’s own pointer-sharing, recovered as identity semantics. What a `Diag` element is *not* is a diagram up to isomorphism: two trees can realize isomorphic diagrams and remain distinct elements, related by a declared side-condition (`alifib_iso`, in the full theory). That choice matches the engine, which stores assemblies and *computes* isomorphism, and it is the honest one for a database: identity of stored data stays structural, and the quotient stays a judgment.

Partiality needs no apparatus. A 0-cell has no boundaries, so `Gen/src` simply has no row for it; there is no nullable column and no sentinel: a boundary a generator lacks is a row nobody asserts, and the axioms only ever demand what presence owes. The same convention carries map holes below.

Everything the engine *decides* about these trees enters as side-condition relations, and the theory *demand*s the judgments where they are owed:

```
alifib_wf      : [d: Diag] -> Prop;    // realizes to a molecule
alifib_pastable : [k: Nat, l: Diag, r: Diag] -> Prop;

ax/wf/diag : forall d : Diag.
  |- [d: d] alifib_wf;

ax/wf/paste : forall k : Nat, l : Diag, r : Diag, d : Diag.
  d = [k: k, l: l, r: r] dPaste
  |- [k: k, l: l, r: r] alifib_pastable;
```

Read `ax/wf/paste` as a well-formedness debt: every asserted paste owes a pastability judgment, and the judgment is discharged by evaluation, not by chase derivation — each of these relations is imported at the top of the file, which classifies it side-condition, and the bounded external procedure behind them is the `alifib` engine. The refusal discipline of §4.6 carries over unchanged: absent the engine, a plan citing these atoms cannot be expressed, and nothing defaults to true.

One derived view shows the chase doing for proof theory what it did for order flow. Which generators — hence which rewrite rules — does a diagram use?

```
Diag/uses : [d: Diag, g: Gen] -> Prop;

chase ax/uses/gen : forall g : Gen, d : Diag.
  d = [g: g] dGen
  |- [d: d, g: g] Diag/uses;

chase ax/uses/paste_l : forall k : Nat, l : Diag, r : Diag, d : Diag, g : Gen.
  d = [k: k, l: l, r: r] dPaste, [d: l, g: g] Diag/uses
  |- [d: d, g: g] Diag/uses;
```

(Its mirror `ax/uses/paste_r` walks the right subtree.) This is the Shippable of the proof theory: a table nobody writes, entailed by structure, answering the question a proof library wants indexed — which rules does this proof depend on?

## 4.7.2 Incidence, and maximality without negation

A paste tree is a recipe. The shape it realizes is an *oriented graded poset*: cells graded by dimension, each cell covering its faces with one of two signs, input or output. Chapter 6 develops the S-complex vocabulary this book uses for such data and notes that oriented graded posets embed as its Boolean instance; here that instance appears as concrete rows. A materialized shape is a `Cplx`; its cells carry a grade and an index within the grade (the engine’s canonical, normalization-derived order), and the two signed covering relations land as two ordinary relations:

```
Cell/cplx : Cell -> Cplx;
Cell/dim  : Cell -> Nat;    // grade
Cell/idx  : Cell -> Nat;    // index within the grade
```

```

BdryIn  : [hi: Cell, lo: Cell] -> Prop;   // lo is an input face of hi
BdryOut : [hi: Cell, lo: Cell] -> Prop;   // ... an output face

ax/scx/sign_disjoint : forall hi : Cell, lo : Cell.
  [hi: hi, lo: lo] BdryIn, [hi: hi, lo: lo] BdryOut
  |- false;

ax/scx/d2_pp : forall z : Cell, y : Cell, x : Cell.
  [hi: z, lo: y] BdryOut, [hi: y, lo: x] BdryOut
  |- exists w : Cell. [hi: z, lo: w] BdryOut, [hi: w, lo: x] BdryIn
  or exists v : Cell. [hi: z, lo: v] BdryIn, [hi: v, lo: x] BdryOut;

```

ax/scx/sign\_disjoint is a denial in the style of ax/no/zombie: one sign per covering edge. The second axiom is new territory. It is one quarter of the boundary-parity law, the sign-aware face of  $\partial \circ \partial = 0$ : every two-step signed path admits a two-step path of the opposite parity class between the same endpoints. Its conclusion holds a genuine disjunction, so the axiom is not chase-eligible — there is no least fixpoint to compute when the theory offers a choice — and the engine treats it exactly as §4.3 treated repairs: as a judgment carrying a menu. Back there the menus had length zero; this one has length two, and it earns its keep as a checked structural law rather than a derivation rule (the reference manual’s account of per-axiom modes is §5.7.2). The law is not hypothetical housekeeping: exporting all twenty-two example files alifb ships, with included modules and every generator and named diagram materialized, yields 37,988 complexes, and sign-disjointness and the parity law hold across them with zero exceptions (receipt at the chapter tail).

Now the idiom this section promised. “ $x$  is maximal” means “ $x$  has no coface”, and that sentence wants negation in a premise, which the geometric fragment deliberately lacks. Store the complement instead:

```

Cell/top      : Cell -> Prop;   // asserted: maximal (no coface)
Cell/covered  : Cell -> Prop;   // derived: has a coface

chase ax/cell/covered_in : forall hi : Cell, lo : Cell.
  [hi: hi, lo: lo] BdryIn
  |- lo Cell/covered;

chase ax/cell/covered_out : forall hi : Cell, lo : Cell.
  [hi: hi, lo: lo] BdryOut
  |- lo Cell/covered;

ax/cell/top_not_covered : forall c : Cell.
  c Cell/top, c Cell/covered
  |- false;

ax/cell/top_or_covered : forall c : Cell.
  |- c Cell/top or c Cell/covered;

```

Three moves. *Generation*: Cell/covered is an ordinary monotone view, derived from the boundary rows. *Exclusivity*: a denial keeps the asserted mark and the derived view disjoint. *Coverage*: a disjunctive law says every cell falls on one side or the other — judged, like the parity law, never fired. Between them, “maximal” becomes queryable vocabulary, its complement kept disjoint by the denial and exhaustive by the disjunction, and no premise ever had to say *not*. The pattern is general; alifb merely needs it constantly, because boundaries of pasting diagrams are defined through maximality.

### 4.7.3 Maps, holes, and the axiom that must not fire

An alifb map assigns, to each generator of a domain type, a diagram in a codomain type; alifb’s proof workflow builds such maps interactively, leaving *holes* — unassigned generators — to be filled as the proof progresses. In rows, a hole costs nothing:

```

AMap/src : AMap -> AType;
AMap/img  : [g: Gen, m: AMap] -> Diag;   // PARTIAL: a hole is an
                                           // absent row
AMap/total : AMap -> Prop;                // asserted mark

```

```

ax/map/total : forall m : AMap, s : AType, g : Gen.
  m AMap/total, s = m AMap/src, s = g Gen/type
  |- exists i : Diag. i = [g: g, m: m] AMap/img;
}

```

Filling a hole is an ordinary append — one new `AMap/img` row — so an interactive proof session is event-sourced by construction, and “what did this map look like before the fill” is a replay question like any other. The axiom is the interesting resident. `ax/map/total` is chase-eligible on its face: single disjunct, an existential the restricted chase knows how to witness. Firing it would be a disaster in slow motion. The chase would mint a fresh, contentless `Diag` for every open hole of every map marked `total`, “satisfying” totality by inventing images that mean nothing — when what totality means for user data is a *judgment* that the user’s own fills eventually discharge. So the axiom stays report-marked, a checked debt rather than a generator (one of the eighteen reports in the check transcript above), and the invented-witness power of §4.3 stays where it belongs: on axioms whose existentials denote obligations the database itself owns, like `ax/ship/manifest`’s missing shipment. Choosing per axiom, in the source, with the default on the safe side, is what the mode marks are *for*.

#### 4.7.4 One diagram, end to end

Here is a complete `alifib` type, small enough to watch cross the seam whole. Two composable arrows, a third arrow, and one 2-cell rewriting the pasted path into it (juxtaposition is `alifib`’s shorthand for pasting along the shared boundary of highest shared dimension; here `f g` abbreviates `f #0 g`):

```

@Type
Compose <=< {
  x, y, z,
  f: x -> y,
  g: y -> z,
  h: x -> z,
  step: f g -> h
}

```

Figure 4.1: The 2-cell `step` of the `Compose` type, twice over. Left, the pasting diagram: `step` rewrites the pasted path `f #0 g` into `h`. Right, the shape it realizes, an oriented graded poset drawn as a Hasse diagram: solid covering edges are input faces ( $\partial^-$ , the `BdryIn` rows of §4.7.2), dashed ones output faces ( $\partial^+$ , `BdryOut`). Seven cells in grades of sizes (3, 3, 1), nine signed edges — row for row, the complex the transcripts below carry.

Save the listing as `compose.ali` at the repository root. The export bridge (built once with `cargo build --release` in `vendor/alifib`; §4.7.5 gives it a proper tour) elaborates the file with the engine’s own loader and interpreter — boundaries checked, shapes realized — and `--check` stops there, printing a summary. The first line is the file’s module root, a type holding nothing here; the one map on the second line is the identity self-map the engine mints for every type, which §4.7.5 returns to:

```

$ vendor/alifib/target/release/alifib-export compose.ali --check

```

```
compose.ali: type - 0 generators, 0 diagrams, 0 maps (0 holes), 0 complexes
compose.ali: type Compose - 7 generators, 0 diagrams, 1 maps (0 holes),
                        7 complexes
warnings: 0
```

Ill-formed input stops at this gate with the engine's own diagnostics: declare oops: `f f -> f` (pasting `f` onto itself along a boundary the types do not share) and the export exits nonzero with “Failed to paste diagrams: boundaries do not match”, pointing at the offending span. Nothing unchecked reaches the rows.

Dropping `--check` emits the interchange document (§4.7.5 specifies it):

```
$ vendor/alifib/target/release/alifib-export compose.ali -o compose.json
wrote compose.json (7616 bytes)
```

Two slices of it, whitespace refolded to the book's measure and content bytes as emitted — the step generator, whose source is the paste tree itself:

```
{ "name": "step",
  "dim": 2,
  "src": { "paste": 0, "l": { "gen": "f" }, "r": { "gen": "g" } },
  "tgt": { "gen": "h" } }
```

and the materialized shape of step, the right-hand panel of Figure 4.1 as data (grades bottom-up; `faces_in[d-1][p]` lists the input faces, at grade  $d-1$ , of the  $p$ -th cell at grade  $d$ , as indices into the canonical order):

```
{ "of": { "kind": "generator", "name": "step" },
  "sizes": [3, 3, 1],
  "faces_in": [ [[0], [1], [0]], [[0, 1]] ],
  "faces_out": [ [[1], [2], [2]], [[2]] ],
  "labels": [ ["x", "y", "z"], ["f", "g", "h"], ["step"] ] }
```

The import half turns the document into instance rows against the Alifib theory. Watch the paste tree become constructor rows, with hash-consing visible (`f` and `g` each occur once as leaves, then the paste refers back to them):

```
$ python3 theories/tools/alifib_interop.py import compose.json \
  -o compose.rows.txt
wrote compose.rows.txt (221 lines)
```

Operations 44 through 50 of that listing:

```
op[ 44] elta sort=G<alifib/Diag>                               // Diag: f
op[ 45] funa fun=G<alifib/dGen> args=[L16] value=L44          // dGen f
op[ 46] elta sort=G<alifib/Diag>                               // Diag: g
op[ 47] funa fun=G<alifib/dGen> args=[L20] value=L46          // dGen g
op[ 48] elta sort=G<alifib/Diag>                               // Diag: (f #0 g)
op[ 49] funa fun=G<alifib/dPaste> args=[nat:0, L44, L46] value=L48
op[ 50] funa fun=G<alifib/Gen/src> args=[L28] value=L48 // src of step
```

and, at the listing's tail, the last three of the figure's nine signed edges — the top cell's own — as boundary rows (L196 names the step cell; L181, L186, L191 the `f`, `g`, `h` cells):

```
op[207] rela rel=G<alifib/BdryIn> args=[L196, L181]
op[208] rela rel=G<alifib/BdryIn> args=[L196, L186]
op[209] rela rel=G<alifib/BdryOut> args=[L196, L191]
```

These are ordinary instance rows; engine instruments consume them as such. The census verb, for one, seeds them under the theory and analyses which function symbols' merges the derivation leans on (a dry-run instrument, it desugars the function symbols the chase bridge refuses — its first line counts them):

```
$ geolog census theories/Alifib.geolog --rows compose.rows.txt
merge-reliance census - 1 file(s), 1 rows listing(s), 24 arrow(s) desugared
:
seeds: 44 elements, 166 rows
```

Finally, back out. The projection inverts the import, and the `.ali` renderer turns the interchange back into source, with every paste parenthesized so the engine re-reads the same binary trees:

```
$ python3 theories/tools/alifib_interop.py project compose.rows.txt \
-o back.json
$ python3 theories/tools/alifib_interop.py to-ali back.json -o back.ali
$ sed -n 5,14p back.ali
@Type
Compose <=<= {
  x,
  y,
  z,
  f: x -> y,
  g: y -> z,
  h: x -> z,
  step: (f #0 g) -> h
}
$ python3 theories/tools/alifib_interop.py accept compose.ali
ACCEPT: CLEAN
```

The `accept` verb at the end is the round trip run as a test, both directions at once; the next subsection says what it checks.

#### 4.7.5 Converting data to and from alifib

This subsection is written for readers who keep data in alifib’s own formats — its maintainers first among them — and want the crossing stated precisely: where the bridge lives, what travels over it, the commands for each direction, what survives a round trip, and what is checked on the way in. The reward for crossing is everything this chapter has shown: types, diagrams, proofs, and their realized shapes as rows in a substrate with signed content-addressed commits, merge by set union, derived provenance views like `Diag/uses`, and a schema that is data in the same log.

**The bridge, and why it lives where it does.** alifib’s structural core (paste trees, oriented graded posets) is a private module, and the engine’s own output surfaces render for display: boundary expressions as strings, paste chains flattened, no incidence tables. A faithful exporter therefore has to live *inside* the engine crate, where crate-private data is reachable, and drive the interpreter itself; anything else would be a reimplementation, trusted precisely where it should not be. The geolog-alpha repository vendors a pinned copy of the engine carrying that exporter as one additive module (`vendor/alifib`; provenance, upstream commit, and the complete patch list are in `vendor/alifib/VENDOR.md`, and the patch is written to be upstreamable as-is). The bridge builds from a fresh clone:

```
$ cd vendor/alifib && cargo build --release
$ ./target/release/alifib-export --help
usage: alifib-export <file.ali> [--type NAME] [--all-modules]
      [--complexes none|gens|named|all] [-o OUT] [--check]
```

By default the root file’s module is exported with every named type, and shapes are materialized for every generator and named diagram; `--complexes none` keeps the export purely syntactic, `--type` restricts to one type, `--all-modules` includes what the file includes. Output is deterministic — two runs are byte-identical — because every collection rides a canonical order: generators ascending by (dimension, name), which is also a dependency-safe declaration order, since a generator’s boundary leaves are strictly lower-dimensional; diagrams and maps by name; cells in the engine’s own normalization order.

**The interchange document.** One JSON document per export, versioned by its first key. In sketch (field names exact, values elided):

```
{ "alifib_interop": 1,
  "generator": "alifib-export (geolog interop bridge)",
  "source": "<root file basename>",
  "modules": [
    { "path": "<path relative to the root file>",
```

```

    "types": [
      { "name": "...",
        "generators": [ { "name", "dim", "src?", "tgt"? } ],
        "diagrams": [ { "name", "dim", "tree" } ],
        "maps": [ { "name", "domain", "images", "holes" } ],
        "complexes": [ { "of", "sizes",
                        "faces_in", "faces_out", "labels" } ] ] ] },
    "warnings": [ "..." ] }

```

A generator's `src/tgt` are present iff its dimension is positive. `diagrams` carries the type's named diagrams: `let` bindings and proofs stored from interactive sessions. A map's domain is either `{"type": t}` or `{"module": m}`; its `images` are filled assignments, its `holes` the open ones, each hole optionally carrying a conditional image and metavariable boundary trees. A complex records whose shape it is (`of`), its per-grade extents (`sizes`), both signed face lists indexed as in §4.7.4, and per-cell generator labels. Boundary terms and diagram trees share one grammar, four node shapes in total:

|                                             |                                                                                                         |
|---------------------------------------------|---------------------------------------------------------------------------------------------------------|
| <code>{"gen": "f"}</code>                   | a single-cell diagram                                                                                   |
| <code>{"paste": k, "l": t1, "r": t2}</code> | <code>t1 #k t2 --</code> the engine's own binary node, never flattened or re-associated                 |
| <code>{"hole": "g"}</code>                  | a map hole's metavariable (appears only in hole boundary terms)                                         |
| <code>{"labels": [...], "ldim": n}</code>   | loud fallback for a diagram with no paste history at its top dimension; counted in warnings, not a term |

**Into geolog.** `import` compiles a dump to instance rows; `--type` restricts, as with the exporter:

```
$ python3 theories/tools/alifib_interop.py import mine.json -o mine.rows.txt
```

The output is a plain-text listing of numbered operations in the meta-schema's instance vocabulary, three kinds in all: `elta` mints an element of a sort, `funa` asserts a function row, `rela` a relation row. Arguments are literals (`nat:0`, `str:"step"`) or backreferences (`L48` names the element minted by operation 48; forward references are ill-formed by construction). The `G<alifib/...>` tokens cite the Alifib theory's declaration identities, so the listing is meaningful against any store holding that revision. Each distinct paste tree becomes one `Diag` element per type, however often it recurs — the hash-consing of §4.7.1, performed at import time. The importer runs a structural self-check before writing (every reference points backward and at an element; every external token lies within the Alifib signature) and stamps the verdict in the header; the committed listings under `theories/generated/` are regeneration-checked against their generators by the repository's check script, so drift between tool and artifact is loud.

What admission means, in layers: the importer's self-check is the shallow layer; the theory's demand axioms are the deep one. Every imported element owes the judgments of §4.7.1 — well-formedness, pastability, roundness — and those side-conditions are discharged by the engine, which is to say: by re-elaboration. Running `alifib-export mine.ali --check` is the decision procedure, executed on the way out of alifib, before the rows exist; the incidence laws (sign-disjointness and parity) are additionally checkable without the engine, and `alifib_interop.py verify-scx mine.json` does so directly on a dump. Engine instruments consume the rows today (`geolog` check for theory-side conformance, `geolog census` for merge-reliance analysis, the meta-rows loader in the repository's test suite for loader conformance), and the one-verb facade of §4.4 seals theory *sources*; an admission seam that seals imported instance rows like these behind the same store is the piece still in design tense, and this paragraph sheds the qualifier when it lands.

**Out of geolog.** Two verbs invert the import:

```
$ python3 theories/tools/alifib_interop.py project mine.rows.txt -o back.json
$ python3 theories/tools/alifib_interop.py to-ali back.json -o back.ali
```

`project` rebuilds an interchange document from rows. It is deterministic, total on the import's image, and loud off it: unknown functions or sorts, dangling references, a `Diag` with no constructor row, a map marked total with absent images (inside the database that state is a judged, standing debt; the exporter never emits it, so the projection holds it off the image), an index at or beyond its grade's extent, a count mismatch

between declared extents and cells, non-adjacent boundary rows — each is a named rejection, not a silent drop. `to-ali` renders an interchange document as `.ali` source: every paste fully parenthesized, so the engine re-reads the same binary trees; identifiers outside `alifib`'s lexical grammar sanitized deterministically, with the name map recorded in the header comment; maps emitted as module-level `let total` declarations; and the identity self-map the engine generates for every type is skipped, since elaboration regenerates it. The acceptance judge for this direction is `alifib` itself: the round-trip witness re-elaborates the rendered source with the engine's own parser and loader and compares the re-export against the original document.

**What survives, what degrades.** Surviving a full round trip, per type, structurally intact: generator names, dimensions, and boundary trees as exact binary pastes (no re-association); named diagrams and their assemblies; map images and holes, as assignments over the domain's generators; complexes cell for cell — extents, both signed face lists, labels. Degrading, each by design and each documented in the tools' headers: map *names* are not carried by rows, so maps re-emerge under fresh names; a conditional image (one recorded on a hole but awaiting boundary resolution) degrades to a plain hole, and the engine re-derives the constraint on re-elaboration; maps whose domain is a whole module are skipped with a note, the module system being surface elaboration that the interpreter flattens before the proof theory begins; display metadata (index blocks) does not travel; execution traces sit outside interchange version 1 — the Trace sort of §4.7.1 is the landing site reserved for them.

**The acceptance harness.** Both witnesses run as one verb per file (`accept`, as in §4.7.4), and over a fixed ten-file corpus spanning the shipped examples' feature surface — abstract machines, higher-categorical developments, hole workflows, simplicial complexes; the parity measurement of §4.7.2 separately covered all twenty-two files:

```
$ python3 theories/tools/alifib_interop.py accept-corpus
BinaryNat.ali: CLEAN
EckmannHilton.ali: CLEAN
:
Hole_examples.ali: CLEAN
LambdaSigma.ali: CLEAN
CORPUS: 10/10 clean
```

Witness one: export, import, project; the projection must reproduce the interchange up to the documented degradations. Witness two: export, render to `.ali`, re-elaborate with the engine, re-export; the second document must match the first up to the recorded name map — boundary trees, hole sets, and complexes cell for cell. Every round-trip claim this subsection has made is one of those comparisons or one of the named rejections. Readers extending the interchange — traces are the obvious next passenger — extend the witnesses first; the harness is the contract.

## 4.8 The scorecard

Where the SQL stack wins today, plainly: **Throughput and maturity.** Kafka moves gigabytes per second and Feldera maintains complex view cascades incrementally, while this preview's chase is a correct, differentially-tested reference implementation whose incrementality so far covers violation views only. **Aggregates and windows.** Streaming SQL's core vocabulary, not native to the geometric fragment (explicit constructions or the ground seam, at tutorial scale). **Operations.** The surrounding decade of connectors, monitoring, and hiring.

Where geolog wins, plainly: **Views you can audit.** Derived state is entailment, re-derivable and checkable from the log by a third party, with provenance; there is no fold code to believe. **Merge without a protocol.** Set union plus re-derivation, order-free, defined for every pair of replicas, with no per-type merge design and no rebalance to choreograph. **Judgments over exceptions.** Invalid states and pending choices are typed, reportable data with the violated axiom attached, rather than code paths. **Writers you can hold to account.** Signatures, content-addressing, and structural equivocation detection are the data model, not an add-on. **One substrate.** Schema, extension, annotation, and migration are rows in the same log they govern; there is no registry to drift.

Compose the two lists and the position comes out plain. At this preview, geolog has the right shape for

systems of record where auditability, principled merge, and schema-as-data carry the value, at volumes where a reference-grade engine suffices. It is also built deliberately so that the fast paths can arrive without the trust story changing (the lane law; the kernels repository).

## 4.9 Composing systems, and where QTSL begins

The order flow of this chapter is one system. The book's larger programme composes systems, with shared boundaries, wiring diagrams, and the population and fusion of components, and it states *temporal* claims about the composites. Those claims are not of the form “no cancelled order has shipped”; that is a state property, and you watched a denial say it. They look instead like “every placed order is shipped or refunded within thirty days, with probability at least  $p$ .” Those are claims the chase alone cannot check and the event log alone cannot even state. Stating them is QTSL's job, and certifying them against models is the rest of this book: the systems vocabulary in chapter 12, the composition patterns in chapter 13, and the zero-to-certificate path in chapter 7. You now hold the substrate they all stand on: a log whose truth is structural, tables that are theorems, and a schema that is data.

# Reference Manual

DRAFT

This chapter is the systematic account of `geolog` as shipped in the `geolog-alpha` repository: the source language and its grammar, the normalization pipeline and its registry, the elaboration fragment the `geolog` verb carries, the chase and its judgments, the meta-schema, and the substrate contracts — commits, storage, sync, the ground seam, and capabilities. The Quick Start (chapter 3) and the Tutorial (chapter 4) teach by example; this chapter specifies. It restates none of their walkthroughs and cites them where an example earns more than a rule would.

Three reading conventions govern everything below.

**Claim discipline.** Normative present tense describes behaviour shipped and tested in the repository as of this edition's receipt passes (2026-07-21 through 2026-07-31, recorded at this chapter's source tail). Designed-but-not-shipped behaviour appears only in clauses explicitly marked *design tense*, each naming where the design lives today. Every quoted error message and every transcript fragment in this chapter is the verbatim output of a real run against the committed tree (receipts in this chapter's source tail).

**Authority order.** The `geolog` binary is ergonomics and composition over constituent crates, and its own crate documentation states the rule this manual inherits: where a behaviour differs between the facade and a constituent, the constituent is right and the facade has a bug. Accordingly, each section below names its authority — the crate (or committed theory file) whose documented, tested behaviour it restates. Where this manual and that source disagree, the source wins and the disagreement is a defect in this manual.

**Scope.** This manual covers the public `geolog-alpha` tree. The engine library supports strictly more than the command-line fragment (§5.8); the manual covers both, and says which surface each statement binds.

## 5.1 Lexical structure

Authority: `crates/geolog-normalize/src/lex.rs`.

Theory text and instance blocks share one tokenizer. Input is processed line by line; a `//` begins a comment (outside a string literal) that extends to the end of the line and is discarded. Tokens, longest match first:

```
two-char    ::= ">" | "<" | "<=" | ">=" | "!="
single-char ::= "<" | ">" | "=" | "+" | "*" | "[" | "]" | "(" | ")"
            | "," | ":" | "." | "{" | "}" | ";"
integer     ::= digit+
string-lit  ::= "'" (any scalar except "'" or newline)* "'"
identifier  ::= starter continuer*
```

The identifier alphabet is Unicode-open, and the operator characters are a closed ASCII set, so the two are disjoint by alphabet rather than by any gating rule. A *starter* is an ASCII letter, `_`, a non-ASCII alphabetic scalar (Greek letters,  $\ell$ , ...), or one of the math-letterlike symbols  $\partial$  and  $\nabla$ ; a *continuer* is any starter, an ASCII digit, `_`, `/` (so `ax/path/edge` and `Marking/count` are single tokens), or a script extender — the superscript and subscript digits and signs, and the primes. Script extenders continue tokens and never start them:  $\partial^+$  is one token, and a detached superscript at token start is a tokenization refusal, so  $\partial^+$  (with a space between) cannot silently mean anything. String literals are single-line and carry no escapes; the grammar admits them in exactly one position — contraction specs in law bodies (§5.15) — and every other

position refuses them downstream. There are no negative-number literals and no block comments in the theory grammar. Anything else stops the tokenizer with a hard error naming the offending text.

The reserved words of the theory grammar are:

```
| forall exists not iff or false theory extends
| Set Prop Index Fin DynTensor List
```

`Fin` and `Index` name the same bounded-index type (`Fin` is the ratified spelling, `Index` the legacy alias — §5.3). `Tensor` is not reserved, and no longer names a surface type at all: the shape-in-type tensor former lives in the meta-schema tier (§5.9.2), and the surface tensor type is the keyword `DynTensor` (§5.3). `instance` is likewise not a keyword of the theory grammar: an instance *block* is recognized by the file splitter (§5.2), one layer up, and the same word doubles as an optional postfix marker on model-of types (§5.3), recognized contextually. The mode marks *chase*, *report*, and *refuse* (§5.7.2) are contextual in the same way — recognized only as a statement’s leading token: *chase* : ...; is still an ordinary declaration named *chase*.

## 5.2 Source files

*Authority:* `crates/geolog/src/input.rs`.

A `.geolog` file carries two strata: *theory text* and *instance blocks*. Before parsing, the file is split by a deliberately minimal scanner that tracks `//` comments and brace depth, and recognizes the word *instance* only at brace depth zero, at an identifier boundary on both sides. Each instance `... { ... }` span is extracted whole (an unclosed block is a hard error); the remaining text — with each extracted span replaced by whitespace of identical line structure, so diagnostics keep their line numbers — is handed to the normalization pipeline verbatim. Consequences worth stating: the word *instance* inside a comment or inside any braced body is ordinary text; theory declarations and instance blocks may interleave freely at top level; and the theory grammar remains entirely the normalizer’s business — the splitter never interprets theory text.

## 5.3 Theories and declarations

*Authority:* `crates/geolog-normalize/src/parse.rs` (*grammar*) and `crates/geolog-normalize/src/ast.rs` (*abstract syntax*).

Theory text is a sequence of theory declarations:

```
| theory-decl ::= "theory" NAME param* ["extends" NAME] "{" statement* "}"
| param      ::= "(" NAME ":" ("Set" | NAME) ")"
| statement  ::= [mode] NAME ("," NAME)* ":" statement-body ";"
| mode       ::= "chase" | "report" | "refuse"
```

A theory header may bind parameters, name first: a (`X` : `Set`) group binds a sort parameter, and a (`N` : `PetriNet`) group — whose second name must be a theory declared earlier in the file — binds a *model-of* parameter, a model of that theory. (An earlier binders-before-name header order parses as a deprecated spelling; see `--strict`, §5.14.) Every statement is an optional mode mark, one or more comma-separated names sharing one signature, a colon, a body, and a semicolon. The statement’s *kind* is dispatched on its name: **a statement whose name begins with `ax/` is an axiom** (§5.4); a statement opened by the contextual keyword `law` is a law member of the aggregation surface, whose grammar this edition defers (§5.15); every other statement is a declaration. The prefix does grammatical work rather than expressing a naming convention: a sequent-shaped body under a name without the `ax/` prefix is parsed as a declaration and fails (verified: `my/rule : forall ... stops with syntax error: unparseable type at line 4: forall ...`, the cited line being the statement’s own). The Quick Start’s remark that slash-names are ordinary identifiers remains true — the slash is an identifier character (§5.1) — but the two-character prefix `ax/` is what makes a statement an axiom. The mode mark decides whether an axiom fires or judges (§5.7.2); the AST carries the *authored* mark, so rendering preserves the source form, and a mode mark on a declaration head is a hard error naming both the mark and the head (the message names `ax/` and `law` as the two homes a mode can mark).

Declaration bodies:

```

sort-decl  ::= NAME ":" "Set" ";";
record-decl ::= NAME ":" "{" field ("," field)* "}" "->" codomain ";";
unary-decl ::= NAME ":" type "->" codomain ";";
curried-decl ::= NAME ":" "(" NAME ":" type ")" "->"+ codomain ";";
const-decl ::= NAME ":" type ";";
field      ::= NAME ":" type
codomain   ::= "Prop" | type
type       ::= NAME
              | term ("Fin" | "Index") -- a sort (or a theory: model-of)
              | NAME "DynTensor"      -- bounded index (n elements)
              | NAME "List"           -- dynamic tensor over an element sort
              | NAME "List"           -- finite sequences over an element sort
              | arg+ NAME ["instance"] -- model-of application

```

Braces name record domains. (The bracket spelling `[f: v]` of earlier corpora still parses by default while the committed corpus ports to braces; under strict parsing it is a deprecation error pointing at the brace form, and `geolog fmt` prints the canonical respelling — §5.14.) A curried signature of named binders normalizes to the record form at parse, so the two spellings declare the same relation or function; an unnamed curried binder is a hard error. A declaration with codomain `Prop` declares a *relation*; any other codomain declares an element-valued *function* (a `const-decl` is the nullary case: a constant of its sort). Relations come in two domain shapes at the surface: *record* (named fields; field order as written is preserved for display, but fields are name-keyed, never positional) and *unary* (one anonymous argument). There is deliberately no surface form for a zero-argument proposition: `Flag : Prop`; parses as a constant declaration of a (nonexistent) sort `Prop` and is refused downstream (§5.6). A proposition wants at least one argument, or it wants to be a fact.

Two type forms are new with the aggregation surface, and both are codomain vocabulary for the loader's stratum rather than the chase fragment's. `DynTensor` is the *dynamic* tensor type over an element sort — shape carried in the value, where the meta-tier `Tensor` former carries shape in the type (§5.9.2); tensor values are side-condition payload, never term-language citizens. A theory name in type position means “a model of that theory”: bare (`base : G`; under a `(G : Graph)` parameter), or applied to arguments (`initial_marking : n0 Marking`), with an optional postfix `instance` keyword as an explicitness marker — neither spelling is canonical, and the source printer preserves the author's choice. A third form belongs to the list former (§5.9.2): `Str List` is the finite-sequence type over an element sort, postfix like `Index` and `DynTensor` and taking one element sort only (`Str List List` is a syntax error), with list values consumed through the `len/at/concat` ground roster as side-condition payload — never term-language citizens. The surface element scope is the builtin ground sorts: a list codomain at a declared sort is refused by the normalizer (verified: `List element "A"` is not a builtin ground sort (`v1` surface scope)), and the wire tier's wider element scope, nesting included, arrives with its own surface spelling rather than by fall-through. The `v1` chase bridge refuses all three forms (§5.6).

`extends` names a parent theory. In the single-file pipeline the parent must be declared in the same file, and extension is realized by elaborating the whole file as one union (§5.6); in the committed-revision pipeline extension is a `TheoryExtends` row with its own conformance rules (§5.9).

**Builtin ground sorts.** The authoring idiom accepts a roster of ground sorts in declarations without a `Set` statement — `Q`, `Z`, `Nat`, `B`, `Str`, `ENNRat`, `Shape`, `Timestamp`, `Bytes`, `PeerId`, `CommitId`, and the aggregation surface's staged registry sort `Accum` (`crates/geolog-normalize/src/builtin.rs`) — together with the literal-dtype correspondence that types bare integer literals (`q/z/nat/...`), the builtin comparison and arithmetic vocabulary the grounding moves compile onto (§5.4.3), and the aggregation tier's staged arithmetic (`nat_mul`, `succ`). This roster is, `Accum` aside, the normalizer's *accepted* subset of the engine's primordial sort tier (§5.9.2) — `Accum` belongs to the deferred aggregation surface (§5.15), not the primordial tier; the command-line chase fragment is narrower still and refuses ground sorts at elaboration (§5.6).

## 5.4 Axioms and geometric normal form

*Authority:* `crates/geolog-normalize` (`parse.rs`, `normalize.rs`, `lint.rs`); the normal form is also stated, as *schema*, by the meta-schema (§5.9).

### 5.4.1 The axiom grammar

```

axiom      ::= [mode] AXNAME ":" ["forall" binders "."] [premise] "|-" conclusion ";"
binders    ::= NAME ":" type ("," NAME ":" type)*
premise    ::= item ("," item)*
item       ::= atom
            | "not" atom
            | "(" item ")"
            | "exists" binders "." premise          -- premise only
            | "forall" binders "." iff-group        -- pattern moves
conclusion  ::= "false"
            | disjunct ("or" disjunct)*
disjunct    ::= ["exists" binders "."] item ("," item)*
atom        ::= term [cmpop term]
cmpop       ::= "=" | "!=" | "<" | "<=" | ">" | ">="
term        ::= prod ("+" prod)*
prod        ::= postfix ("*" postfix)*
postfix     ::= primary NAME*                      -- application chain
primary     ::= "{" NAME ":" term ("," NAME ":" term)* "}" -- record
            | INTEGER                                -- literal
            | NAME                                    -- variable

```

Grammar facts with semantic weight: `or` binds loosest in a conclusion, and an existential's scope never spans an `or` — each disjunct carries its own `exists` prefix, so the surface conclusion is literally the normal form's shape (a disjunction of existentially quantified conjunctions). An `exists` group in a premise swallows the remaining premise items up to the turnstile. Terms are postfix application chains — `m p` Marking/count reads “Marking/count applied to (`p` applied to `m`)” — with `*` binding tighter than `+`, record literals in the same brace idiom declarations use (brackets remain the parsed legacy spelling during the corpus port, §5.3; on the aggregation surface square brackets instead delimit contraction index groups in law bodies, §5.15), and bare integer literals (typed later by the normalizer). `| - false` declares a *denial*: a rejection rule, the empty disjunction.

### 5.4.2 Geometric normal form

The engine consumes *geometric* theories, and the normal form is the central definition of this chapter:

**Definition 5.1** (geometric sequent). A geometric sequent is a universally quantified entailment whose premise is a finite conjunction of atoms and whose conclusion is a finite disjunction of existentially quantified finite conjunctions of atoms; the empty disjunction is  $\perp$  (a denial). An atom is an equation between terms or a relation applied to a term; the quantified variables are typed at declared sorts.

Geometric sequents are the sequent fragment of geometric logic [127, Part D1]; database theory knows the single-disjunct case as tuple- and equality-generating dependencies [72]. The authoring idiom of §5.4.1 is richer than this — `not`, `exists` in premises, `forall`-`iff` groups, comparison operators, arithmetic sugar, Index types. The normalizer (§5.4.3) compiles every departure down to Definition 5.1 by a registered move or rejects it loudly; the geometric linter then mechanically enforces the normal form on the normalizer's own output — premise a conjunction of atoms; conclusion a disjunction of existentially quantified conjunctions; no residual Index; no untyped literal; every relation declared *and* classified (§5.4.4); every atom well-sorted. Pipeline failures are collected and reported together, never truncated to the first.

### 5.4.3 The normalization moves

Each move is either total on its registered pattern or a loud error; nothing passes through half-rewritten. In source order of the pipeline:

- **Premise negation**, discharged by atom class. A negated *side-condition* atom needs no logic at all: side-conditions are decision procedures, and a decision procedure is negation-complete, its complement being the same evaluator with the verdict flipped. The discharge is therefore exact and in place —  $\neg S \wedge P \vdash C$  becomes *not*/ $S \wedge P \vdash C$ , with the complement relation registered automatically (move census: negated premise side-condition *S* discharges in place as *not*/*S*). A negated equation at a ground comparison sort has its complement in the builtin vocabulary already:  $\neg(a = b)$  at `Q` or

Nat becomes `q_ne` or `nat_ne`, in place. The one genuinely logical case is a negated *ordinary* atom, or an equation at a declared sort. Ordinary vocabulary is derivation-defined, so no procedure can decide its complement; instead the atom *crosses the turnstile* as a new leading conclusion disjunct.  $\neg R \wedge P \vdash C$  becomes  $P \vdash R \vee C$ : the classical-to-geometric compilation (move census: negated premise ordinary atom *R* crosses the turnstile). Read at the fixpoint, the crossed sequent says exactly what the classical sentence said: wherever *P* holds, *R* holds or *C* does. What it deliberately does not offer is negation-as-failure. The crossed head is a disjunction, so the axiom is no longer chase-eligible (§5.7.1), and a chase mark on it is a load refusal: a rule that fired on the *current* absence of a derivable row would be unsound against every later derivation, so no move is owed to that reading. Under report, the crossed disjunct is judged like any other menu (§5.7.6).

- **Pattern rewrites** (forall-iff groups). Extensionality, difference, and intersection shapes over a registered membership relation rewrite to auxiliary mask side-condition atoms; not on a membership atom in a conclusion rewrites to a registered negation-free witness atom. All four require registry entries (§5.4.4); an unregistered shape is a hard error, because auxiliary vocabulary is an obligation on downstream evaluators and is never minted silently.
- **Exists-hoist.** An exists group in a premise hoists to universal variables — sequent semantics:  $(\exists x. P) \vdash C \equiv \forall x. (P \vdash C)$ .
- **Index erasure.** Every `n` Index type erases to Nat plus a generated range obligation (a binder guard atom, or a generated `ax/range/*` axiom).
- **Grounding.** Comparison and arithmetic sugar compiles onto the builtin roster at ground sorts: `!=` to `q_ne/nat_ne`, `</=>` to `q_lt/q_le/nat_lt`, `+/>` to `q_add/q_mul`, with `>/>=` flipped by operand swap. There is no grounding at declared sorts: `a != b` over a declared sort *A* is a hard error (verified: no ground builtin for `!=` at sort *A* (the `!=@A` case would need a builtin-roster addition)). Disequality of declared-sort elements is not expressible in the fragment — deliberately: the chase’s equality discipline is congruence (§5.7.5), and a general disequality atom over invented elements is exactly the kind of vocabulary that would need an evaluator nobody has priced. (A negated premise *equation* at a declared sort is a different matter: it crosses the turnstile as an equality conclusion, per the premise-negation move above, so the classical constraint remains sayable even though a disequality atom does not exist.)
- **Literal typing.** Bare integer literals receive their dtype from context (`q:3/1`, `nat:2`, ...); an untypable literal fails the linter.

An axiom touched by any move is renamed with an `_n` suffix, so normalized output re-normalizes to itself with an empty move log. The pipeline’s guarantees, carried by its test suite: two-run determinism (byte-identical listings), idempotence (`normalize ; normalize = normalize`), linter-cleanliness of every output, ground meaning preservation (the grounding moves agree with direct evaluation of the source operators on random ground instances), and committed fixture goldens per move. `iff` at sequent top level (which would become two sequents) is unimplemented and errors loudly if it ever fires.

#### 5.4.4 Imports, classification, and roster totality

*Authority:* `crates/geolog-normalize/src/imports.rs` (the import surface), `crates/geolog-normalize/src/registry.rs` (the registry value both surfaces feed).

Every declared Prop-valued relation is classified, exactly one of:

- **ordinary** — derivation-defined: populated by assertion and by the chase, and by nothing else;
- **side-condition** — decided by a bounded external procedure (the ground seam, §5.12, or a registered auxiliary evaluator), never derivation-defined.

This is *roster totality*: every relation has a decided evaluator, and it holds *by construction* — the obligation is discharged by syntax instead of by hand. The classification lives in the source file itself. `ordinary` is the default, declared by writing nothing; a side-condition is declared by an `import` item naming its provider:

```
import std.{0, q_lt};
import <provider>.<relation>, ...;
```

The two namespaces do different work. An `import std` item authorizes *builtin ground vocabulary* used by name — sorts like `Q` and `Nat`, comparisons like `q_lt` — and a name outside the builtin roster refuses at once, listing the importable names. Any other namespace declares each named relation a side-condition awaiting that provider, bound at the ground seam (an unknown provider is not an error at check time: binding is deferred, and an unbound side-condition atom simply cannot be discharged — refusal over guessing, downstream). Import items are position-free top-level items, so multi-file closures concatenate; re-importing a name under the same namespace is idempotent, and importing one name under two namespaces refuses — one name, one provider. A relation or function declaration that reuses a builtin *vocabulary* name is legal only as an exact-signature shim of that builtin: same-named, byte-equivalent to what the engine itself would say. A builtin *sort's* name admits no shim at all — it is fully reserved, and a local sort takes another name (verified: `sort Q (declared in T): builtin ground sort names are reserved` — the builtin `Q` is ambient (`import std.{Q};` declares the usage), so a local sort must take another name). Both reservations are kind-local (the sort and vocabulary namespaces never meet), so a relation may take a builtin sort's name, and a declared sort may take a builtin relation's. Builtin comparison relations and the normalizer's own minted auxiliaries are side-conditions without import lines. Under `--strict`, builtin ground vocabulary used by name demands its `import std` header even in files that otherwise import nothing.

The *pattern registry* is the second classification surface, today a library-level one: it names, per rewritten relation, its *membership* reading (which field is subject, which is index), and the auxiliary relation each registered move targets (extensionality: 2 fields; difference and intersection: 3; negation-witness: the relation's own arity). Registry construction validates all of this — missing membership entries, unregistered auxiliaries, arity mismatches, and duplicate auxiliaries are errors before any theory text is touched. Pattern registrations have no source-level surface yet; the library's registry value carries them (the normalizer's fixtures/ include pattern-bearing specimens).

A line-oriented registry *file* (`--registry`) was the classification's original carrier; it is deprecated, retained for the migration era only. The one-authority law binds at the registry's content, and classification is the content it guards: a registry whose lines classify relations refuses to combine with a source that declares imports (verified: this source declares imports AND an external registry carries relation classification — classification has one home; ...), while a pattern-only registry file composes with an importing source — its aux names kept clear of the imported ones (verified: `aux relation ...` collides with an imported name — `aux mask vocabulary` is the normalizer's, never imported), a collision being classification smuggled back in aux costume. The line format also carries the pattern registrations of the paragraph above (their one textual carrier while patterns have no in-source spelling), and a pattern registration is no second classification authority.

## 5.5 Instance blocks

*Authority: crates/geolog/src/facts.rs (grammar), crates/geolog/src/seed.rs (semantics).*

```
instance-block ::= "instance" NAME ":" NAME "{" item* "}"
item           ::= elem-decl | record-fact | bare-fact
elem-decl      ::= NAME ("," NAME)* ":" NAME ";"
record-fact    ::= "{" NAME ":" NAME ("," NAME ":" NAME)* "}" NAME ";"
bare-fact      ::= NAME NAME ";"
```

Tokenization is the theory lexer's, so comments and identifiers mean the same thing in both strata. The header names the block and the theory it instantiates; the named theory must be declared in the same file. Items are element declarations and facts; a record fact's brace lists `field: element` pairs and then the relation; a bare fact (a `Marked`;) applies a unary-kind relation. Facts must be written in the relation's own shape — a record fact on a unary relation, or vice versa, is an error naming the mismatch. Braces are canonical here as in declarations: this grammar is what `geolog fmt` prints, and the formatter's output re-parses (verified: the respelled Quick Start file chases end-to-end, its report byte-identical to the bracket original's), while the bracket spelling `[f: a] Rel`; remains the accepted legacy form until the committed corpus ports to braces.

Semantics, in seeding order (source order — element numbering in transcripts is deterministic):

- **Elements are declared before use.** A fact referencing an undeclared name is an error, never a silently minted element (verified: ``P`` fact references ``ghost``, which is not a declared element – declare it first (``ghost` : A;`); elements are never minted silently).
- **Fields are exact.** A record fact must supply every declared field, no extras, no repeats, no defaults; each element’s sort must equal the field’s declared sort.
- **Union semantics across blocks.** An element name declared in two blocks at the same sort denotes one element; duplicate facts are idempotent. A name redeclared at a *different* sort is an error (verified: element ``a`` redeclared at sort ``C`` but already declared at sort ``A``). This is the merge story — set union of commits, then re-derivation (§5.11.1) — at authoring scale; the Tutorial’s two-writer example is built on it.

Surface syntax is a view: this block form is the command line’s authoring view of an instance, and the durable form is signed commits with content-addressed element identity (§5.10).

## 5.6 Elaboration: the v1 command-line fragment

*Authority: crates/geolog/src/elab.rs; the crate-level docs of crates/geolog/src/lib.rs state the fragment.*

The bridge from the normalized authoring idiom to the engine IR covers, in v1: **sorts**, **Prop-valued relations** (record or unary domains), and **geometric axioms whose atoms apply relations to variables**, equality conclusions included. Everything else the idiom can express is refused with an error naming the construct and, where one exists, the supported spelling of the same intent. The engine library supports more than this bridge; the bridge grows by deliberate widening, never by silent acceptance.

Elaboration takes the file’s theory declarations as *one single-file closure*: the union of every declaration in the file, with extends between in-file theories honoured by that same union. Consequences: an instance block may reference any declaration in the file’s closure regardless of which theory block carries it; duplicate sort or relation names anywhere in the closure are errors; and extends naming an out-of-file parent is refused (verified: theory ``Child`` extends ``Ghost``, which is not declared in this file – cross-revision extension rides the committed-revision pipeline (geolog-meta-rows / geolog-revision), not the v1 CLI bridge).

The operative refusals, each verified against the committed binary:

- **Element-valued functions** (any declaration with a non-Prop codomain, constants included):

```
function symbol `f` (codomain `C`): element-valued functions are engine
IR the v1 bridge does not carry – spell the function as a relation plus
a functionality axiom (two rows in the premise, an equality in the
conclusion), the idiom the committed theories use (e.g. `Marking/count`
+ `ax/count/functional` in theories/PetriNet.geolog)
```

The named idiom is normative: a function  $f : A \rightarrow B$  is spelled as a relation  $F[a : A, b : B]$  plus  $\forall a, b_1, b_2. F[a, b_1], F[a, b_2] \vdash b_1 = b_2$ , and the chase’s congruence closure does the rest (§5.7.5). `Flag : Prop`; lands in this refusal too (its “codomain” parses as the sort `Prop`); see §5.3 for why no zero-argument proposition form exists.

- **Ground sorts in declarations** — any field, argument, or binder sort not declared `Set` in the file, the builtin roster included:

```
relation `R` field `n` names sort `Nat`, which this file does not
declare – the v1 bridge elaborates single-file closures over declared
`Set` sorts only (ground sorts such as `Nat` arrive with the ground
seam; see crates/geolog-ground)
```

This is also where `Index` types land operationally: the normalizer erases `n Index` to `Nat` (§5.4.3), and the bridge then refuses `Nat` as above. The worked discipline for doing real arithmetic *without* the seam — counts as explicit elements on a ladder, chase-derived — is `theories/PetriNet.geolog`.

- **Tensor, list, and model-of types** — the codomain forms of §5.3 beyond plain sorts are loader vocabulary, and the bridge carries a dedicated refusal for each. A `DynTensor` anywhere in a declaration:

relation ``P`` field ``x`` uses a ``Tensor`` type — tensor payloads are side-condition territory, not v1 bridge vocabulary

A model-of member, on today's routes, is caught upstream by the element-valued-function refusal instead (its codomain is not `Prop`); the bridge's own instance-valued arm — refusing instance members as loader territory — stands behind it as defensive depth, per the posture above. A List codomain is caught upstream the same way; a List in a *field* position reaches the bridge's own list arm (verified: relation ``P`` field ``x`` uses a ``List`` type — list payloads are side-condition territory (the `{len, at, concat}` roster), not v1 bridge vocabulary).

- **Ground literals and term-level application in axiom atoms**, and nested records in argument positions: refused naming the axiom. Under the current pipeline these arms are defensive depth — declaration-level refusals and normalizer typing catch the practical routes first — and they stay, per the bridge's stated posture: a bridge that assumes its input is well-formed fails silently the day the assumption breaks.

Axiom-side checks (variables bound by `forall` or an enclosing `exists`; sorts agreeing with declarations; fields exact; no variable bound twice; no existential shadowing an outer variable) are belt-and-braces re-verification of what the normalizer already established, kept for the same reason.

## 5.7 The chase

*Authority: crates/geolog-chase — classify.rs, chase.rs, instance.rs, judgment.rs. The engine has no silent path: every outcome below is either a derived row, a typed refusal, or a reported judgment.*

### 5.7.1 Sequent classification

Repair arity is computed from syntax alone, by one total function, and every engine consults it — no runtime data participates. The conclusion is normalized to disjunctive head form (`Conj` distributes over `Disj`; a  $\perp$  conjunct annihilates its branch), and:

| head disjuncts | class       | chase posture                                    |
|----------------|-------------|--------------------------------------------------|
| 0              | denial      | never fires; violations are judgments            |
| 1              | canonical   | fires (invents witnesses) — the regular fragment |
| $\geq 2$       | repair menu | never auto-fired; surfaced as a branch point     |

One carve-out is permanent: a head that reaches an existential over an *immutable* sort (an infinitary disjunction — the engine IR's `InfDisj`) is never chase-eligible regardless of arity, because an infinitary disjunction is in no way a unary disjunction; no witness-invention strategy for it can ever be sound. The refusal is loud and names the axiom.

### 5.7.2 Modes: the author's word on firing

Whether an axiom fires is not inferred from its shape: it is *authored*, per axiom, by the mode mark of §5.3. The three marks:

- **chase** — a derivation rule: the axiom fires, inventing witnesses and asserting conclusions. Only a chase-eligible axiom (§5.7.1: canonical head, no `InfDisj`) may carry the mark; chase on an ineligible axiom is a load refusal naming the axiom by its *source* name (verified: axiom `ax/pick/one` is marked ``chase`` but is not chase-eligible ...; mark it ``report`` (judge) or ``refuse`` (gate), or reshape its head).
- **report** — a constraint: the axiom never fires; its violations and would-be firings surface as judgments (§5.7.6).
- **refuse** — a constraint that additionally gates local authoring: report's judgment semantics plus the local write gate of §5.8. On the file path there is no commit to gate, so its violations render exactly as report's.

**An unmarked axiom means report** — the least-dangerous default (chase creates rows and refuse blocks commits; report only judges), so derivation is always an explicit authorial act. Denials sit naturally under report: a denial never fires in any mode, and its violations are phase-2 judgments (§5.7.3) regardless.

The marks map onto the engine’s per-axiom trichotomy (§5.8): chase → Chased, report → Monitored, refuse → Enforced. geolog chase runs a file under this authored partition by default, recovering each axiom’s mark from the normalized declarations with three alignment checks per axiom (count, name, binder vector) so any drift between the normalizer’s and the bridge’s axiom order is a loud refusal, never a silent mode reassignment.

**The legacy flattener.** `--mode chased|monitored` (§5.14) survives for corpora not yet carrying explicit marks, applying one run-level policy to every axiom: under chased, every eligible axiom fires and a disjunctive head is a theory-load error before the loop ever runs (verified, on an unmarked file: theory load refused: axiom ax#0 is not Chased-eligible: repair arity is Menu(2); only a single-disjunct (canonical) head with no InfDisj binder may run under mode Chased – declare it Monitored instead, or split/simplify the axiom); under monitored, eligible axioms fire and disjunctive heads surface as branch points. On a file carrying *any* explicit mark the flag refuses, naming the marked axioms (verified: `--mode` conflicts with this file’s explicit surface marks: ax/path/edge (chase), ... – drop the flag to honor the marks): a mark is the author’s word, and a global flag that silently promoted a report-marked axiom into the firing set would be the exact hazard the marks exist to close — worst case, an equality conclusion merging the very elements it was written to police. Where the flag does run, the flattening is announced on stderr.

Engine-level load refusals name axioms positionally (ax#i): engine sequents carry no name field — names are metadata, held by the caller (or, in the durable pipeline, by meta-schema rows) — and the facade maps indices back to source names wherever it holds them (§5.7.7); the bare positional form above is the legacy flattener’s path showing the engine’s own words.

### 5.7.3 The two-phase run

A chase run has exactly two phases, and the separation exists for one reason: *a transient judgment can never be persisted as if final*.

**Phase 1** fires only canonical axioms, to a fixpoint or the iteration bound. The loop’s continuation condition is instance mutation only — discovering a violation is never a reason to keep (or stop) iterating. **Phase 2** is one evaluation pass of every denial and every menu axiom against the *final* canonical instance, bindings resolved through the final congruence. A menu whose missing witness is supplied by the very last canonical firing is therefore never recorded stale, and every judgment binding is a canonical representative of the final fixpoint.

Hitting the bound is not an error: the instance-so-far is returned, a non-termination judgment is recorded (with both the iterations run and the bound), and phase 2 still reports whatever holds of the partial instance — validity is explicitly indeterminate, not omitted (verified: no fixpoint within budget: 5 iterations (bound 5) – raise `--budget`, or the theory does not saturate on this instance (unbounded generation is a real outcome, reported rather than guessed at)).

### 5.7.4 Restricted semantics and invention

Canonical firing is the *restricted* chase [62]: for each binding of an axiom’s universal context that satisfies the premise, the engine first evaluates the conclusion as a query under that binding — **if any witness already exists, it does not fire**. Only a witnessless binding invents: one fresh element per existential binder, then the conclusion’s atoms are asserted (relation rows as derived rows; equations via congruence, §5.7.5). The Tutorial’s shipment example is the behaviour in one line: the order with a recorded manifest got no invention; the order without one got exactly one fresh ?Shipment.

Every element carries an immutable creation-provenance record, written once and never rewritten by any merge: seeded (EDB) elements carry caller-supplied provenance bytes (at command-line scale, the declared name; in the durable pipeline, a commit-addressed leaf), and chase-invented elements carry the firing axiom’s index, the context-bound elements of the firing (in context order), and the fresh binder’s

ordinal within the axiom. Derived rows are distinguished from asserted rows throughout (§5.7.7). One invariant worth its ink: for a premise whose own existential (hoisted per §5.4.3) admits several matches over the same context binding, the first firing’s witness satisfies the rest — so exactly one witness, with a context-only provenance term, ever exists per context binding.

### 5.7.5 Equality and congruence

Equality is computational, not annotational: the instance maintains a union-find congruence closure in the style of Nieuwenhuis and Oliveras [189]. An equational conclusion firing merges two elements’ classes; everything known about either — rows, provenance-bearing derivations, later firings — holds of the merged class. Tuples are stored raw and canonicalized through the current union-find at every read, so a merge never rewrites tables. The report renders a merged class by joining its seeded names (`sf_record=wh_label; b=c`) and accounts for it in the carrier arithmetic (3 seeded, 1 merged by congruence — verified transcript). The functionality idiom of §5.6 plus this machinery is how *geolog* has functions without function symbols in the v1 fragment. (Chase steps interleaved with congruence closure are also the computational core of datalog-with-equality and equality-saturation engines [20, 247], the nearest kin to this engine in the evaluation literature.)

### 5.7.6 Judgments

A judgment is one thing the chase found that a silent-success engine would have swallowed — the authority module’s own one-line definition of the type. The chase’s loud outputs, exhaustively, each carrying the axiom’s identity and, where applicable, the witnessing binding with canonical elements:

- **Denial violation** — a denial’s premise is satisfied at the fixpoint:  $\vdash \perp$  for this binding. Reported, never dropped, never repaired.
- **Branch point** — a menu axiom’s premise is satisfied with no existing witness for *any* disjunct. The payload carries the menu (the disjuncts themselves, as data); the engine picks nothing. Under the legacy run-level flattener a menu has length  $\geq 2$ ; menu-of-one branch points (a forced repair, surfaced rather than fired — a menu of 1 repair) arise wherever the per-axiom partition holds an *eligible* axiom to report (§5.7.2, §5.8) — an unmarked derivation rule’s would-be firings surface this way.
- **Non-termination** — the bound was hit (§5.7.3).

Judgments are results, not errors: a run that produces them completed, exits with the judgment exit code (§5.14), and its instance is real — the event-sourcing posture (invalid states representable, detected, repaired by further ordinary commits) held formally. The Tutorial’s merge chapter is the worked argument for why this posture, and not write-rejection or automatic repair, is the design.

### 5.7.7 The report

*Authority: crates/geolog/src/report.rs.*

The chase verb renders every carrier, every row, and every judgment, through the source file’s own names; nothing about a judgment is summarized away. The normative rendering facts, seven of them:

- each sort prints its canonical carrier size with the seeded count, the count invented by the chase, and the count merged by congruence, followed by a merged: line naming merged seeded-name groups;
- each relation prints in declaration order, rows sorted and deduplicated after canonicalization, with seeded/derived tallies;
- derived rows — rows not in the canonicalized image of the seeded baseline — are marked +;
- rows print in the relation’s own shape (record, bare, or bare name for nullary);
- chase-invented elements render as ?Sort.n in first-encounter order;
- side-condition relations are tagged [side-condition];

- judgments print the axiom's *source* name and the binding in context order, a branch point adds its menu size, and a clean run ends `fixpoint: reached`, no judgements — the model is saturated. (with a count of invented elements when there are any).

## 5.8 The engine beneath the command line

*Authority: crates/geolog-chase (mode.rs, weight.rs, view.rs, delta.rs, plan\_ir.rs, validity/), crates/geolog-weights. Everything in this section is shipped, tested library surface. The per-axiom mode partition is the one piece the geolog verb now reaches — through the surface marks of §5.7.2; the rest is not reachable from the verb yet.*

**Per-axiom modes, and Enforced.** The engine's mode system is a per-axiom assignment over the trichotomy **Chased** / **Monitored** / **Enforced**, with an eligibility-keyed ambient default (chase-eligible  $\Rightarrow$  Chased, everything else Monitored — reproducing the legacy run-level default, so that default is semantics-preserving) and validated explicit overrides: a Chased override on an ineligible axiom is a typed error; Monitored/Enforced overrides on *eligible* axioms are honoured by a firing partition — the axiom never fires, and its would-be firings surface as menu-of-one branch points (the forced repair, surfaced, never auto-fired). The surface marks lower onto this same machinery, as a *total* explicit assignment — every axiom's effective mark, unmarked resolved to report first — so on the file path the author's word, never eligibility, decides firing, and the ambient default decides nothing; the ambient default remains the semantics for library callers that override selectively. Enforced is Monitored plus the *local write gate*: an admission verdict over a finished chase result rejects any local commit whose resulting fixpoint carries an Enforced violation. The commit-vs-sync seam is the caller's, and its asymmetry is doctrine: the gate binds **local commit paths only** — states arriving by sync or merge are admitted with their judgments recorded, because gating sync admission on validity would cost true merge and history-as-authority (§5.11.1). Modes differ in *when* validity is enforced, never in what validity is. The adjudicator refuses to grade a mode assignment against a run that was not partitioned under that same assignment — the silent-vacuity class (an axiom fired in phase 1 repairing its violations before any judgment could exist) is rejected loudly, never admitted vacuously. The meta-schema carries the same trichotomy as rows (Axiom/monitored, Axiom/enforced, at most one per axiom; absence of both is the ambient default) — §5.9.

**Weights.** The engine is parameterized over an ordered-semiring provenance-weight algebra (crates/geolog-weights): a weighted run integrates each derived row's weight from its derivation structure, a reweight pass recomputes after tombstoning, and death-at-zero holds — the weighted-alive set after tombstone + reweight equals a from-scratch Boolean chase on the surviving facts (protested as a differential). The Boolean rung *is* the unweighted engine: `run_chase` stays pinned to  $W = \text{bool}$  and is byte-identical to the weight-blind engine.

**Deltas, maintained views, and the plan IR.** The delta bus makes the engine's unit of change data (element, row, and function deltas in batches). The view engine compiles violation views — the failing set of each denial, kept current under row deltas, never recomputed from scratch — and verifies itself against from-scratch reference evaluation (a divergence is a reportable defect, and the rebuild invariant of the repository's battery backs it at replay scale). Compiled views lower to a tensor-contraction plan artefact with canonical, digest-citable bytes, a dense reference evaluator, and an accelerator emission harness; the reference evaluator is the verdict authority throughout (the lane law, §5.12).

**Per-commit validity.** The validity layer (crates/geolog-chase/validity/) assembles per-commit validity judgments over chase results: which commits does this judgment implicate — well-posed exactly because every derived row and every invented element carries its firing history (§5.7.4). Wiring it into the storage pipeline end-to-end is design tense (the factoring is committed; the Tutorial states the same status).

## 5.9 The meta-schema

*Authority: theories/GeologMeta.geolog — the meta-schema’s normative statement, from whose text this section is condensed; where they disagree, that file wins. The committed genesis golden (§5.10.5) is its reference instance; the generator tool (theories/tools/geologmeta\_gen.py) re-derives and byte-compares both directions as a drift alarm in CI.*

geolog is a logical framework, not an expressive logic. GeologMeta is the fixed schema of geometric theories: one meta-schema, frozen at genesis; every theory — including the proof calculi the companion repositories ship — is an ordinary instance: delta rows against GeologMeta, carried by ordinary signed commits. Schema, extension, annotation, and migration therefore live in the same substrate they govern (the Tutorial’s “no second database”).

### 5.9.1 Sorts and rows

Nine schema sorts: Theory, Sort, Fun (function or relation — relationality is a mark, not a second sort), Field, Axiom, Var, Disjunct, Atom, Term. Table 5.1 carries the declaration vocabulary over them, with partiality as documented there (“partial” in its notes column means the row may be absent, and absence is meaningful — Codd’s I-mark discipline [45], never “unknown yet”).

| subject  | rows                                                                                                                                                                                                                                 | notes                                                                                                                                                                                                 |
|----------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Theory   | TheoryExtends[child, parent]<br>TheoryRevises[new, old]<br>(no Theory/name)                                                                                                                                                          | multi-parent legal; extends graph acyclic<br>revision intent; acyclic; causal half lives in deps<br>identity is the element; discovery naming lives above                                             |
| Sort     | Sort/name, Sort/theory<br>Sort/immutable<br>Sort/builtin_code                                                                                                                                                                        | carrier opaque to the chase (choose, never create)<br>partial: builtin tier only (§5.9.2)                                                                                                             |

| Var      | Var/premise_of → Axiom<br>Var/bound_in → Disjunct                                                                                                                                                                                    | universal variables, scoped to the whole axiom<br>existential variables, scoped to one disjunct; exactly<br>one home (partition law)                                                                  |
| Disjunct | Var/sort, Var/name<br>Disjunct/axiom → Axiom                                                                                                                                                                                         | name is presentation only, hash-excluded<br>one branch of the conclusion; zero disjuncts on an<br>axiom = rejection rule                                                                              |
| Atom     | Atom/premise_of → Axiom<br>Atom/concl_of → Disjunct                                                                                                                                                                                  | premise atoms hang on the axiom itself<br>conclusion atoms hang on a disjunct, never on the<br>axiom; exactly one home                                                                                |
| Term     | Atom/eq_lhs, Atom/eq_rhs<br>Atom/rel, Atom/rel_arg<br>Term/var<br>Term/app_fun, Term/app_arg<br>Term/is_record, RecordField[rec, field, value]<br>Term/lit_q, lit_z, lit_nat, lit_b, lit_str,<br>lit_shape, lit_enrat, lit_timestamp | equation atoms<br>application atoms; exactly one kind<br>variable<br>application (arg absent iff nullary)<br>records; empty record is the explicit mark<br>one typed literal row per primordial dtype |

Table 5.1: The meta-schema’s declaration vocabulary, by subject sort (§5.9.1).

Domain shapes are discriminated by which rows exist — nullary: neither Fun/arg\_sort nor Field rows; unary: Fun/arg\_sort; record: Field rows.

The axiom encoding deserves a picture, because it has one level the sequent notation hides (Figure 5.1). The premise hangs directly on the Axiom element: premise atoms by Atom/premise\_of, universal variables by Var/premise\_of. The conclusion sits one level deeper. A conclusion is a disjunction of existentially quantified conjunctions (Definition 5.1), so each branch is its own Disjunct element, tied to the axiom by Disjunct/axiom; a conclusion atom names its *disjunct* as home (Atom/concl\_of), never the axiom, and an

Figure 5.1: The Tutorial’s `ax/ship/manifest` ( $\forall o. \text{Shippable}(o) \vdash \exists s. \text{ShippedVia}(o, s)$ ) as meta-schema rows. Premise structure homes on the Axiom element; conclusion structure homes on a Disjunct, one element per branch of the disjunction. Which side of the turnstile an atom or variable lives on is read off the function row it carries, and the axiom’s repair arity is its Disjunct count — here one, the canonical shape.

existentially bound variable does the same (`Var/bound_in`). An axiom’s premise is therefore the *set* of atoms homed on it, its conclusion the *set* of its disjuncts, and its repair arity (§5.7.1) is its Disjunct count: zero is the empty disjunction, a rejection rule; one is the canonical, chase-eligible shape; two or more is a repair menu.

Field-name uniqueness per Fun and RecordField uniqueness per (record, field) are load rejections, deliberately not unification axioms: in a store whose rows are signed declarations, silently merging independently minted declarations would erase provenance — collisions are loud.

The meta-axioms, exhaustively (all fifteen; three shapes recur — entailment, rejection pair, and the (disjoint, exhaustive) *partition law* pair stating “exactly one”):

| axiom                                                                  | shape       | states                                      |
|------------------------------------------------------------------------|-------------|---------------------------------------------|
| <code>ax/meta/builtin_immutable</code>                                 | entailment  | coded sorts are immutable                   |
| <code>ax/meta/side_condition_relational</code>                         | entailment  | side-condition $\Rightarrow$ relational     |
| <code>ax/meta/relational_no_codomain</code>                            | rejection   | a relation never has a codomain             |
| <code>ax/meta/codomain_exhaustive</code>                               | disjunctive | every Fun is relational or has a codomain   |
| <code>ax/meta/arg_sort_fields_disjoint</code>                          | rejection   | unary and record domains exclude each other |
| <code>ax/meta/mode_marks_exclusive</code>                              | rejection   | at most one explicit mode per axiom         |
| <code>ax/meta/var_home_{disjoint, exhaustive}</code>                   | partition   | every Var has exactly one home              |
| <code>ax/meta/atom_home_{disjoint, exhaustive}</code>                  | partition   | every Atom sits on one side of $\vdash$     |
| <code>ax/meta/atom_kind_{disjoint, exhaustive}</code>                  | partition   | equation or application, never both/neither |
| <code>ax/meta/term_{var_app, var_record, app_record}_{disjoint}</code> | rejection   | representative term-kind disjointness       |

(`ax/meta/codomain_exhaustive` is also the schema’s own fixture for a disjunctive conclusion with an existential; the three term-kind rejections are representatives — the full mechanical pairwise family, the 28 literal pairs included, is elaboration-time conformance rather than schema text.)

**The testable negative.** What is deliberately absent is structural, not policed: no Formula sort and no Conj/Disj/Exists/Not/Iff nodes (nesting beyond geometric normal form is unrepresentable); no negation node and no iff node (both are authoring-side moves, §5.4.3); no Index/dependent-type node (erased upstream); no InfDisj node (Sort/immutable on the binder’s sort carries the distinction); no proof or derivation sorts (proofs of object logics are rows of object theories — the logical-framework doctrine); no weight or provenance slot (engine configuration, not schema); no annotation vocabulary (annotations are ordinary relations in ordinary extension theories — metadata needs rows, never a schema revision).

## 5.9.2 The primordial sort tier

Thirteen builtin ground sorts are declared as ordinary Sort rows in the genesis instance, marked immutable, and fixed forever: Q, Z, Nat, B, Str, ENNRat, Shape, Timestamp, Bytes, PeerId, CommitId, and the genesis-pinned extension-band straddle pair Date and Interval. Beside the thirteen sorts stand three sort *formers*, structural rather than declared — no Sort row, no declaring element; like the naturals themselves, they are simply available:

- **Fin** — the bounded-index former, an indexed family  $\text{Nat} \rightarrow \text{Sort}$ : for each natural  $n$ ,  $\text{Fin}(n)$  is the  $n$ -element index sort. These are the sorts that index tensor axes (an axis of extent  $n$  is indexed by  $\text{Fin}(n)$ ); the surface grammar’s bounded-index type ( $n$  Index, §5.3) expresses the same idea at authoring scale, though today the normalizer erases it to  $\text{Nat}$  plus range obligations (§5.4.3). Cell code `0x09` (§5.10.3).
- **Tensor** — the tensor former,  $\text{Shape} \times \text{Sort} \rightarrow \text{Sort}$ : given a shape (a  $\text{Shape}$  value, the list of axis extents) and an element sort, the sort of tensors of that shape with entries at that sort. The element sort may be *any* sort, declared or builtin, not only a numeric one. Canonical form is flattened, and a rank-zero tensor collapses to its single entry. Cell code `0x0A`.
- **List** — the finite-sequence former,  $\text{Sort} \rightarrow \text{Sort}$ , length carried per value:  $\llbracket x \text{ List} \rrbracket = \sum_{n:\text{N}} (\text{Fin}(n) \rightarrow \llbracket x \rrbracket)$  — each value brings its own  $n$ , the  $\text{DynTensor}$  mechanism with rank pinned at one. Positional order is the value (no sorting, no deduplication), and there is no flatness or unit law:  $(x \text{ List}) \text{ List}$  is a distinct, ragged two-level sort, never collapsed. Element scope at this tier is any sort, nesting included; the one adjudicated exclusion runs the other way — a list instance is not admissible as a  $\text{Tensor}/\text{DynTensor}$  *element* in  $v1$ , while  $(x \text{ Tensor}) \text{ List}$  is legal. Former code `0x10`; the surface spelling (§5.3) narrows the element scope to builtin ground sorts; value cells ride dtype code `0x50` (§5.10.3).

A fourth structural former stands beside these three at the wire tier, under its own sort-reference tag rather than a former code: **DynTensor** —  $\text{Sort} \rightarrow \text{Sort}$ , the *dynamic* tensor former, shape carried in the value rather than the type (the  $\Sigma$ -over-shapes reading of  $\text{Tensor}$ ; tag `0x36`, `crates/geolog-envelope/src/former.rs`).  $\text{Tensor}$  is the static reading — shape in the type — and the two are distinct sorts on purpose, never silently interconverted. Of the tensor pair, only  $\text{DynTensor}$  has a surface spelling (§5.3); tensor values are side-condition payload throughout (§5.12).

The tier is ambient: every theory may use it — formers included — in field and codomain positions without an extends edge. Minting an element of a builtin sort is a load rejection; builtin values enter as literals in value cells (§5.10.3).

Genesis-tier ground *vocabulary* equips the primordial carriers with algebraic structure as ordinary declarations (never as type-former firmware), each family’s evaluation semantics pinned in `theories/GeologMeta.geolog` to the corner case:

- **Q field operations** — `q_add`, `q_neg`, `q_sub`, `q_mul`, `q_inv`, `q_div`: exact arithmetic on canonical rationals, no rounding anywhere; partiality is refusal (`q_inv(0)` and division by zero refuse — a field has no answer there, and inventing one is what the exact tier exists to refuse).
- **ENNRat quantale operations** — on the Lawvere rationals  $\mathbb{Q}_{\geq 0} \cup \{\infty\}$ : `ennrat_add`, `_min`, `_max`, truncated minus (`_monus`, the residual of addition), *both* multiplications (`_mul_conj` with  $0 \cdot \infty = 0$  and `_mul_disj` with  $0 \cdot \infty = \infty$  — the two conventions declared under distinct names, never silently harmonized), inversion, residuation, harmonic sum, the two qualitative-mode side-conditions, and exact comparisons.
- **Timestamp** — instants, i64 epoch-microseconds on the POSIX/UTC scale (timezone is presentation, never value); the numeric order as side-conditions; checked displacement arithmetic (`ts_add_us`; overflow refuses, never wraps).
- **Date and Interval** — PostgreSQL semantics, as a tested claim: a corpus of goldens captured from a live PostgreSQL 17 instance is the conformance battery for the calendar family (§5.12); intervals are the three-field months/days/micros value verbatim, never flattened (comparison uses the justified collapse, values do not); refusal wherever PostgreSQL refuses, finite-only.
- **Str, CommitId** — disequality only (`str_ne`, `cid_ne`): string ordering would smuggle a collation choice (presentation, like timezone), and ordering commit hashes would invite misreading bytes as causal order.

Every *other* value format — the floating-point ladder included — is an extension ground format: declared by an ordinary signed revision (never genesis, never a schema revision), carrying a parametric spec over ordinary roster rows (byte width, exponent and mantissa bits, bias, NaN discipline), with wire codes from the extension band and operation dispatch bound to the declaring revision. `ax/meta/builtin_immutable`

quantifies over every coded sort, so extension formats are immutable by the same axiom that binds the genesis roster.

### 5.9.3 Theories as rows; revisions

A theory arrives as a *revision*: a sealed batch of meta-schema rows in one commit body, signed and content-addressed like every other commit (§5.10), dependencies named. Revisions publish whole — an axiom and all its structure land within one revision’s commit set, which is what makes zero-disjuncts-as-rejection well-defined. Identity is structural: a revision hash covers the declaration content (with presentation-only rows, such as `Var/name`, excluded), and a function’s signature hash covers its field names, sorts, and codomain — the identity the ground seam’s dispatch pins (§5.12).

Shipped machinery (`crates/geolog-meta-rows`, `crates/geolog-revision`, `crates/geolog-theories`): the `theory→rows` compiler (byte-identical round-trips on the committed corpora); the sealed-revision conformance loader, whose rejections are loud, named, and collected (one committed negative fixture per live rule); the structural revision and signature hashes with an adversarial vector battery; declaration indexes and cross-revision name resolution; the verified ground-format registry loader; and the programmatic revision-body builder, whose canonical-form invariants (backward local references, bitwise field order, exactly-once name rows) are unrepresentable or checked at build time. The `geolog rows` verb (§5.14) prints the declaration slice of this encoding for any theory file; the committed listings under `theories/generated/` carry complete worked theories (the Petri-net theory is 1,239 ops); and `geolog seal` (§5.14) seals a source file through this machinery — one revision commit carrying the theories as meta-schema rows (its dependency table names the genesis and the ground-comparisons golden, §5.10.5, uniformly — present whether or not the source uses the comparison roster, so the table is never input-dependent), plus a seal companion carrying the source and registry text — deterministically, so re-sealing an unchanged file is a no-op (verified: the second seal reports `store: genesis already present, comparisons already present, revision already present, seal already present`).

## 5.10 Commits: envelopes, bodies, cells, storage

*Authority: `crates/geolog-envelope` (the wire), `crates/geolog-store` (the log), `crates/geolog-ceremony` (the goldens). This section states the shipped encoding — encoding v1 — at the grain a consumer needs; the `crate` module docs carry the byte-exact layouts, and a committed cross-language reference implementation backs the golden vectors.*

### 5.10.1 The skeleton: hash and signature surface

A commit is a two-layer envelope. The **skeleton** is the hash/sign surface: a fixed-layout structure carrying

| field                     | content                                            |
|---------------------------|----------------------------------------------------|
| <code>version</code>      | the encoding version byte (1)                      |
| <code>author</code>       | ed25519 public key, 32 bytes                       |
| <code>deps</code>         | the commit-reference list: 32-byte commit hashes   |
| <code>parent_count</code> | how many leading deps are parents                  |
| <code>ts_claim_us</code>  | claimed timestamp, epoch-μs (a claim, not a truth) |
| <code>message</code>      | optional UTF-8 bytes                               |
| <code>body_hash</code>    | blake3 of the body bytes                           |

`deps` is one list in two segments — parents first, then non-parent content dependencies, each segment sorted strictly bitwise-ascending, duplicates rejected. *Commit identity is content*: `commit_hash` = `blake3(skeleton bytes)`, and the ed25519 signature covers exactly those bytes under a fixed versioned context prefix (`geolog-s4-skeleton-sig-v1`), so no future encoding change can collide signing domains. Canonicity is definitional, in both directions: the writer canonicalizes; the reader, after structural validation, re-encodes the decoded value and requires byte equality with the input (the fixed-point gate) — one value, one byte string, independent of any serializer freedom. A signed skeleton can only be constructed against a body receipt obtainable by durably storing the body, so the format’s sharpest failure mode — a

signed skeleton whose body is absent, a permanently unverifiable dangling commit — cannot arise from the safe API’s normal use.

5.10.2 The body: ops

The **body** is the ops payload. Wire shape: `u16!e body_format || frame bytes`; the format registry has exactly one live entry, and the numbering below is the public truth for this repository:

- 0 — retired before any production bytes existed (a migration lane for a legacy dialect; no wire ever carried it).
- 1 — `BODY_FORMAT_HEXANE_TEMPLATES_V1`: **the only format, and the default**. The canonical op sequence is factored into a template dictionary (one row per cluster of alike ops) plus columnar hole carriers; everything the dictionary hoists is spelled once per cluster, and each op row pays only for its hole values. The factoring is fully *derived* from the content — clustering, per-position carrier modes, and traversal order are laws, not producer choices — and a frame spelling the same rows any other way is refused at decode. The frame ends with the same fixed-point gate the skeleton uses: decode re-encodes and requires byte equality. `body_hash = blake3(body bytes)`.

The op vocabulary:

| op                    | payload                                  | meaning                                     |
|-----------------------|------------------------------------------|---------------------------------------------|
| el <code>ta</code>    | sort reference                           | mint an element of a (mutable) sort         |
| rel <code>a</code>    | relation ref, argument cells             | assert a relation row                       |
| fun <code>a</code>    | function ref, argument cells, value cell | assert a function value                     |
| el <code>td</code>    | target reference                         | delete an element (never a meta-row target) |
| blo <code>b</code>    | format tag, opaque bytes                 | content-addressed bulk (§5.10.3)            |
| unkn <code>own</code> | kind tag, opaque bytes                   | forward-verifiability carry                 |

References are either *local* (an earlier op of the same body, backward only) or *external* (content-addressed, through the deps); names are data (Sort/name rows), never identity. An unknown op kind is preserved byte-for-byte and carried, never dropped and never an error — a reader that predates a kind still parses correctly, because no decode path may silently drop data. Decode enforces hostile-input hygiene throughout: claimed counts are bounded (the op-count ceiling is  $2^{20}$  per body) and bounds-checked before any allocation.

5.10.3 Cells and the dtype registry

Argument and value positions carry *cells*: element references, or literals of the primordial dtypes. The primordial band is complete — `0x00–0x0F`, no holes:

| code | dtype  | code | dtype           |
|------|--------|------|-----------------|
| 0x00 | Q      | 0x08 | Shape           |
| 0x01 | Z      | 0x09 | Fin (former)    |
| 0x02 | Nat    | 0x0A | Tensor (former) |
| 0x03 | B      | 0x0B | Timestamp       |
| 0x04 | Str    | 0x0C | Bytes           |
| 0x05 | ENNRat | 0x0D | BlobRef         |
| 0x06 | ZBig   | 0x0E | PeerId          |
| 0x07 | NatBig | 0x0F | CommitId        |

ZBig/NatBig are multiprecision realizations of  $\mathbb{Z}/\mathbb{N}$  (distinct codes because widening a code’s grammar would be reinterpretation, which the registry’s general law forbids); BlobRef is the out-of-line spelling of Bytes/Str above the inline threshold (a 35-byte content-address cell); CommitId is a reference — a tiny index into the enclosing skeleton’s deps list — and never a context-free literal. The extension band `0x10–0x3F` carries ground formats (the float ladder `0x10–0x16`; the genesis-pinned Date `0x17` and Interval `0x18`), decoded opaquely and validated at closure tier; the absence band `0x40–0x4F` carries typed absence. Values of the list former ride dtype code `0x50` — the first assignment past the reserved bands, sitting out of numeric order because the primordial band was already complete and the former registry’s `0x10` (§5.9.2) falls inside the extension band — validated at decode like the primordials, in two first-byte-discriminated arms: an

*inline* arm (element dtype, count, then length-framed canonical element payloads — scalar elements only: the primordial literal codes minus `Tensor`, `BlobRef`, and `CommitId`) and an *envelope* arm (a 34-byte multihash content address under a dedicated derive-key context), partitioned at 64 KiB in the tensor family’s style; nested lists and non-scalar elements ride the envelope arm, and any cell code  $\geq 0x51$  is a decode error. Over-threshold bulk travels as `blob ops` (format 0 = `blob-raw-v1`) on the same signed-envelope machinery — signing, deps, sync, and equivocation detection inherited, interior deliberately opaque.

#### 5.10.4 The store log

The persistent store (`crates/geolog-store`) appends envelopes and bodies to a log file with a fixed grammar:

```
file      := header record*
header    := b"glog2607" | u32-LE format_version (1) | u32-LE reserved (0)
record    := u32-LE payload_len | u8 kind | payload
kind 1    := ENVELOPE: sig[64] | skeleton bytes
kind 2    := BODY:      raw body bytes (identity = blake3(bytes))
```

There is no per-record checksum, by adjudicated design: every envelope is signature-verifiable and every body content-hash-verifiable — stronger than any CRC — and a checksum cannot repair length-prefix desynchronization anyway. A record length above the 64 MiB ceiling is treated as torn or garbage bytes misread as a length, not as a record. The grammar layer never classifies a failure as crash artefact versus corruption — that is recovery policy, one layer up, which consults a committed hint the grammar deliberately knows nothing about. Header deviations (magic, version, nonzero reserved field) refuse loudly; a future format is a new version behind that gate, never a silent reinterpretation.

#### 5.10.5 The committed goldens and the ceremony

Four signed golden envelopes ship under *theories*: the **genesis** (GeologMeta’s own declaration rows as a signed commit, the root of the graph, `deps = [], message geolog-meta-genesis-v1`); the **ground-formats** revision (the float-format vocabulary, `deps = [genesis]`); the **zones** vocabulary (`deps = [genesis]`); and the **ground-comparisons** roster (`deps = [genesis]`, message `geolog-ground-comparisons-v1`) — the builtin ground-comparison vocabulary (`q_lt, q_le, q_ne, nat_lt, nat_ne`) as a sealed revision, the second dependency of every revision commit `geolog seal mints` (§5.9.3). Each is a deterministic function of its committed structure-normative listing and a *public* seed committed in source: anyone can derive the signing key and reproduce every byte, and cargo `run -q -p geolog-ceremony -- verify --root theories` does exactly that in every CI pass. The key certifies nothing about who signed; what makes these goldens canonical is that they are byte-reproducible from the committed listings by the committed tool. A real deployment mints its own genesis under its own key; the ceremony crate is the complete worked example of how. The genesis is also the meta-schema’s homoiconic fixed point — GeologMeta described as GeologMeta rows — and the generator’s check mode re-derives it from `theories/GeologMeta.geolog` both ways as a drift alarm.

### 5.11 Sync, merge, and equivocation

*Authority: crates/geolog-sync (whose README freezes the contract: objects, invariants, the frontier exchange, the convergence theorem, and a ledger of what is and is not yet claimed) and crates/geolog-envelope/src/equivocation.rs.*

#### 5.11.1 Merge

**Definition 5.2** (merge). The state of a replica is a set of signed commits (a `deps`-closed commit bag). Merging replicas is set union on commits followed by re-derivation of all derived state. Merge is therefore total, commutative, associative, and idempotent; it never conflicts structurally, and admission order does not affect derived state.

A merged state may satisfy some axiom’s violation premise — that is a judgment (§5.7.6), repaired by further ordinary commits, never by a conflict-resolution protocol. The Enforced gate binds local commit paths only (§5.8); gating sync admission on validity is the classic failure this architecture refuses, because it would

cost true merge and history-as-authority. Identity questions inside the merged state (two writers' records denoting one thing) are the theory's business, decided by its equality axioms and computed by congruence (§5.7.5). The rebuild invariant backs the order-independence claim mechanically: the repository's battery diffs incrementally maintained state against from-scratch replay, and a divergence is a release-blocking defect.

### 5.11.2 Replication

Two shipped strata. **Sync v0 — the file mesh:** whole-file, N-device mesh sync of per-device, single-writer, append-only envelope logs plus content-addressed body directories; per-source mirrors and per-run receipts ("silence means broken"); a torn trailing frame is classified by comparing against the prior round's observation (growing source: benign; stable source with a persisting tear: a problem) — a distinction a single snapshot cannot make. **Replay-through-ingestion** is the only path synced envelopes enter a local view: re-verification through the envelope crate's own verify path (no new trust surface), idempotent by commit hash, order-free via a deps-frontier worklist fixpoint.

**Sync v1 — the connected protocol,** layered strictly above v0: a deterministic integer-keyed message codec (strict known-kind decode, unknown-kind skip), frontier-exchange pulls, subscribe push, acknowledged head updates, credit-based flow control, bounded staging, and one door: admission through the same replay path. Equivocation detection runs incrementally during sync and is loud, never a gate.

**Realms and partitions.** Sync is scoped by *realm* — the wire's opaque slice key, today a plain partition name: sessions pull and subscribe per realm, and a realm's head set is an exact summary of its deps-closed store (the crate's `INV-CLOSURE`, which is store-global). A materialized partition must be dependency-closed and revision-closed (no partition splits a semantic revision unit); the reference builder and its checker are separate artefacts, and the checker re-verifies against the store rather than trusting the builder. Dependencies that cross a realm boundary are governed by a per-realm `TransportMode` dial: `refused` (the default), `reported` (the crossing becomes a declared boundary reference), or `repaired` (a locally held foreign dependency's pinned closure joins; a repair that would need a network fetch is a typed refusal). The `repaired` dial also binds at admission: a realm registered `repaired` admits entries whose dependencies are admitted under *other* realms — the dependencies must still be admitted locally, so closure remains store-global — and the dial is local policy, taken at store open and never negotiated on the wire; an undialed peer stages the same entries, a liveness asymmetry rather than a safety one.

### 5.11.3 Equivocation

**Definition 5.3** (equivocation-suspicious pair). Two distinct envelopes from one author, neither of which causally references the other (through deps), form an equivocation-suspicious pair.

Detection is structural — from the bytes alone, no consensus protocol, no quorum — and local to whatever envelope set is supplied: a dep pointing outside the set is "unknown, not reachable," never an error. Two different-bytes envelopes claiming one commit hash refuse loudly (a genuine hash collision or a hostile input; never silently resolved by picking a winner). The envelope crate ships the demonstration as a test — two signed commits claiming the same chain position, exhibited and caught — and the Tutorial locates this in the systems landscape: the offence a broker cannot even state is detected here from the data model. The mechanism, signed hash-linked histories making forks structurally visible, is the same one that makes CRDTs Byzantine fault tolerant [138].

## 5.12 The ground seam

*Authority:* `crates/geolog-ground-api` (the contract) and `crates/geolog-ground` (the reference floor, its first provider).

Ground vocabulary — relations and functions over immutable carriers, decided by procedures rather than stored rows — crosses one seam. **Declaration is data:** ground vocabulary is declared where all vocabulary is declared, as committed theory rows, and resolves to a pinned identity (declaring commit + row index) with a verified signature and, where one exists, the commit hash of the committed evaluation-semantics

row. **Implementation is code:** a *provider* is one value carrying curated claims plus the evaluator over its own entries. **The binder is where they meet**, and it is engine-owned law no provider can bypass or see: every resolved declaration is adjudicated against every provider's claims, with three outcomes per entry —

| status      | meaning                                                                                  |
|-------------|------------------------------------------------------------------------------------------|
| Implemented | exactly one claim verified, committed semantics covered — a dense engine id is allocated |
| Deferred    | declared-but-unbound, safe-fail: no claimant, no semantics row, or a stale provider      |
| Refused     | code and theory disagree (signature mismatch) — the drift alarm, distinct from Deferred  |

Two verified claims on one identity are always an error; provider order is never semantics. Dispatch binds to pinned identities, never names: a same-named impostor declaration gets no oracle and its atoms defer forever. An unbound entry never obtains a dense id, so a compiled plan citing it cannot even be expressed — *compile refusal by construction*, the seam's realization of refusal-over-guessing.

The laws, stated once here and cited by everything that consumes the seam: **purity** (every evaluator is stateless and deterministic per its declared scope — same cells, same outcome, every process, every architecture; a family whose reference uses floating point must pin bit-exact step semantics or cannot be admitted); **the lane law** (an accelerated lane may change cost, never verdicts, and ships with a conformance battery against the always-on scalar reference — a lane that cannot pass its battery does not dispatch); **refusal** (refusal is data, and conservative: under an Enforced axiom, a gate that cannot evaluate must not admit; no seam method panics on validated cells); **no enumeration** (a ground relation filters, never generates; a ground function inverts only where the algebra genuinely determines the missing argument — underdetermined means the engine must not enumerate); and **scope** (pure is the norm; the one typed exception is snapshot-scoped structural relations reading instance rows through an engine-supplied view, with the routing engine-enforced in both directions). Cells cross the seam in their canonical encodings, opaque to the contract; there is no intermediate certificate file format anywhere — a checker is a ground relation evaluating over rows the engine already speaks.

The **reference floor** ships as the seam's first provider: exact arbitrary-precision rational arithmetic, the extended-nonnegative-rational quantale operations, calendar arithmetic with documented, PostgreSQL-conformant semantics (the golden corpus of §5.9.2), and the curated ground-comparison family. The floor's reference path is unconditional; the calendar *functions* sit behind a feature flag whose absence makes their claims absent — declared entries then defer at bind, so **verdicts never change with a feature flag**. Application side-condition families (the proof-calculus checkers of the companion repositories) are application content: they ship as a provider crate owned by the application, composed at build time through this same binder — the only sanctioned coupling between this repository and its first big application. Reaching the seam from the `geolog` command line is design tense; the engine-level seam, the floor, and their batteries are shipped and tested today (the Tutorial's ground chapter walks the same line).

## 5.13 Capabilities

*Authority: crates/geolog-caps.*

Authorization arrives as an algebra over commits, not an access list beside them. Shipped today, as data and replay semantics: capability operations (delegations and revocations) travel as ordinary signed revisions; a normative replay computes which revocations are effective; authorization judgments are query-time and position-relative. The committed design decisions, decision by decision (the authority crate's own phrase):

- a grade lattice `Define < Retract < Admin` per sort — element deletion is the non-monotone direction, so it is strictly higher privilege than minting; the add/delete split of the op vocabulary, lifted;
- a per-relation `Assert` chain sharing no element with the sort chain above bottom, so sort authority and row authority can never satisfy one another;
- dual `Admins` per theory and per instance, with `theory-Read` as the base prerequisite to holding anything effective on a theory's instances;
- a conservative cross-tier stance: no implication in either direction; dormant grants are first-class, queryable, and surfaced by an authoring lint that replay never reads;

- revocations executed in earliest-add seniority (ascending authority-provenance depth, digest-tiebroken), with the auth-order projection carried as data so seniority cannot be padded by packaging;
- edge identity as (revision, index), so identical re-grants in distinct revisions are distinct edges.

*Design tense:* enforcement at the store boundary — wiring these judgments into admission of local commits — is the committed direction; today the algebra, replay, and judgments ship as a library with their property tests, and no store consults them yet.

## 5.14 The geolog command line

*Authority:* `crates/geolog` — `main.rs` for the surface, the modules cited throughout this chapter for each verb's semantics. The end-to-end tests in `crates/geolog/tests/cli.rs` run the book's own transcripts against the committed examples.

```
geolog check      <file.geolog> [--strict]
geolog check      --store DIR [<commit>] [--strict]
geolog chase      <file.geolog> [--instance A[,B...]]
                  [--budget N] [--mode chased|monitored]
geolog chase      --store DIR [<commit>] [--instance A[,B...]] [--budget N]
geolog seal       <file.geolog> --store DIR [--strict] [--repro]
geolog extract    <commit> --store DIR [--referencing] [-o FILE.glc]
geolog restrict   <file.glc> --store DIR --theory SEL [--revision HEX]
                  [-o FILE.glc]
geolog load       <file.geolog> [--strict] [--dry-run] [-d]
geolog load       <file.glc> [--store DIR]
geolog fmt        <file>
geolog rows       <file.geolog>
geolog normalize  <file.geolog> [--strict]
geolog census     <file.geolog>... [--rows LISTING]...
                  [--budget N] [--tsv FILE]
```

**The specified verbs.** **check** runs `parse` → `normalize` → `lint` on the theory text and validates every instance block against the elaborated closure by actually seeding it — exactly the checks `chase` would run, without the `chase` — reporting each stage and then three summaries: a *mode census*, what the file's axioms will do when chased (`modes: 2 chase · 1 report (0 by the unmarked default) · 0 refuse` for the Quick Start theory — so an all-report file, deriving nothing by design or awaiting its explicit-chase port, is legible at a glance); the move census (§5.4.3); and, where the chase bridge carries the fragment, a chase-termination advisory (weak acyclicity) computed under the file's own surface modes — only the chase-marked fragment generates, so a theory of report-marked constraints is termination-trivial by construction, however generative its axioms would be if fired. With `--store`, the same strata run over a sealed source instead of a file, after signature verification and a coherence gate: the sealed source must re-derive the sealed revision rows byte-identically. **chase** seeds the selected instance blocks and runs the chase to a fixpoint, then renders the report of §5.7.7. **rows** prints the theory's declaration slice as meta-schema rows in the committed listings' notation (local refs  $L_n$ , genesis identities  $G_{<...>}$ ), with a closing note counting the axioms that continue as rows beyond the slice; it requires the one-field record spelling for unary relations, because fields are rows with names in the meta-schema (verified: relation `'Marked'` has a unary (anonymous) domain — ... rows emission needs the one-field record spelling: `'Marked : {x: A} -> ...'`).

**The remaining verbs, at citation grain.** Each is shipped and tested; this manual states its role and leaves its full semantics to the named authority. **seal** runs `parse` → `normalize` → `canonical revision rows` → a signed envelope pair in the store: a revision commit and a seal companion (§5.9.3); re-sealing an unchanged file is a no-op. With `--repro` the signature uses the public reproduction seed, making the commit hashes store-independent (pin reproducibility); such commits carry no authorship and must never anchor authority. **extract** writes a commit and its transitive deps from the store to a `.glc` container (magic `geologfl`, self-contained, verified on read rather than trusted); `--referencing` additionally sweeps every store commit whose deps reach the target, so all commits referencing an instance travel together.

**restrict** is theory-fragment restriction of a certificate container — the get side of the delta lens a theory  $B$  extends  $A$  induces: it keeps exactly the rows whose species live in the target theory’s extends-closure (derived from the sealed revision’s own declaration rows), projects the prerequisite table onto the surviving boundary, copies unchanged commits byte-verbatim, re-seals changed ones deterministically with the public reproduction key, and refuses — with a named locus — any container whose kept rows reference stripped content; a pure-fragment container round-trips byte-identical. **load** with a `.glc` argument decodes and verifies the whole container — signatures, body hashes, topological order — then admits it into `--store`; with a `.geolog` argument it stages the theory’s aggregation surface into a live engine (§5.15). **fmt** parses a file, legacy spellings included, and prints the canonical source respelling — the corpus-port instrument (§5.3). **normalize** prints the geometric normal form the engine consumes (§5.4.2) — the committed-golden regeneration verb. **census** is the merge-reliance census over authored equality heads; its method and honesty ledger live in `crates/geolog/src/census.rs`. Authority for all of these: `crates/geolog/src/main.rs` and the modules it names.

**Options.** Classification travels in the source file (§5.4.4), so the file-mode verbs take the file and nothing else; `--registry FILE`, the deprecated migration-era carrier, refuses beside import lines when its registry carries classification (a pattern-only registry composes, its aux names kept clear of imported ones — §5.4.4), and in store mode the flag is refused outright: the registry text travels sealed. `--strict` rejects the deprecated spellings — bracket records, binders-before-name theory headers, `= { instance bodies, : Sort declarations` — each with a pointer at the ratified form (§5.3) — and demands the `import std` header for builtin ground vocabulary used by name (§5.4.4). `--instance A[,B...]` selects blocks by name — the default is every block in the file, as their union (§5.5); naming a missing block is a usage error that lists the blocks present. `--budget N` bounds chase iterations (default 1000); exhaustion is a reported judgment, not an error. By default chase runs each axiom under its authored surface mode (§5.7.2); `--mode chased|monitored` is the legacy run-level flattener for files whose axioms carry no marks, and refuses — naming the marked axioms — on any file that does. chase on a file with no instance block is a usage error that says what to add and points at check for theory-only validation.

**Exit codes.** 0 — clean: the verb completed and, for chase, the fixpoint carries no judgments. 1 — judgments at fixpoint: the run completed and reported violated denials, pending branch choices, or an exhausted budget. 2 — the input never ran: usage errors, unreadable files, pipeline rejections, bridge refusals, seeding contradictions, and engine load refusals. The 1/2 boundary is the error type’s own doctrine: judgments from a completed chase are results, not errors.

**Constituent binaries.** The workspace also ships development CLIs for constituent crates — `glnorm` (the normalizer pipeline standalone), `glstore` (the store log), `glsync` (the file-mesh sync) — documented in their crates; `geolog` is the carryable verb and the only surface this chapter specifies.

## 5.15 Editions: what this manual does not yet state

Open seams, each named with where its truth lives today; a future edition of this chapter absorbs them in this order.

- **The aggregation surface.** The ratified authoring grammar beyond the fragment this manual states — law members (named or anonymous) whose bodies carry contraction index groups and string-literal contraction specs, the arity-typed contraction resolver with its refusal roster (E-RANGE, E-SPEC-\*, E-RPN-\*, E-LAW-\*), and the free-construction instance declarations (parameters, extends targets, and body rows as three seed sources) — is shipped in `crates/geolog-normalize` (the parser module’s documentation is the compact normative summary) and staged into a live engine by `geolog load`, whose emission header marks the engine realization design-tier pending the aggregation-schema promotion. This edition states the surface’s lexical floor and type-grammar hooks (§5.1, §5.3) and defers the rest to the next.
- **The store-backed surface at this manual’s grain.** `seal`, `extract`, `load` of a `.glc` container, the store modes of `check` and `chase`, and `census` all ship today (§5.14); the container grammar, the store-mode conformance rules, and the `census` method are normative in the facade’s modules. A future edition states them at the grain §5.10 gives the envelope.

- **The byte-exact wire grammar.** §5.10 states the encoding at consumer grain; the op-payload grammar, the template-frame channel layout, and the conformance-rule table (load-rejection classes and their fixtures) are normative today in `crates/geolog-envelope`'s module documentation and `crates/geolog-meta-rows`' loader and negative fixtures.
- **Per-commit validity, end to end.** The judgment assembly ships (§5.8); the storage-pipeline wiring and its report vocabulary are design tense.
- **Capability enforcement** at the store boundary (§5.13).
- **The ground seam from the command line** (§5.12): the chase-path elaboration of ground sorts remains refused (§5.6), and the `load` path stages its ground-vocabulary dependencies as roster rows while its engine realization stays design-tier (previous bullet).
- **Cross-revision extends in the facade**, native bounded-index types, and the full evaluation-semantics tables of the genesis ground families (today: pinned, with their corner cases and golden corpora, in `theories/GeologMeta.geolog` and the ground crates' tests).

# Diagrams as Data: S-Complexes

DRAFT

Several strata of this book traffic in *diagrams*. The specification language’s global stratum asserts a certified Morse graph (chapter 14); the hypernet chapter reads every computation as a string diagram (chapter 10); grid certificates decompose state space into cubical cells; and the higher-categorical diagram machinery this project consults runs on oriented graded posets. Each of these is, concretely, a family of cells in graded dimensions plus incidence data saying which cells bound which. Each could therefore grow its own bespoke incidence schema, its own well-formedness checker, and its own subtly different answer to “is the boundary recorded here the boundary the theorem was about?”

The toolkit owns one such object. An *S-complex* is a graded family of finite cell sets whose boundary structure is recorded as a pair of semiring-valued tensors per dimension (one for each orientation sign), satisfying a subtraction-free form of the chain condition  $\partial^2 = 0$ . The semiring parameter  $\mathbb{S}$  is where the genus gets its reach: with Booleans it is incidence, with natural numbers it is multiplicity, with a semiring of *port names* it is a string diagram, and with min-plus dwell bounds its labels carry quantitative dynamics. Well-formedness in every case amounts to a handful of tensor contractions and one semiring comparison per dimension, using the same contraction machinery the rest of the toolkit already trusts (chapter 10, relational-kinship section), so the properties are checkable in bulk, on accelerators, by the engine that checks everything else.

The instinct (diagrams stored as typed incidence data, computed on in bulk) is shared with the attributed  $\mathcal{C}$ -set line of applied category theory, where diagrams are categorical data structures [194] with data-parallel composition algorithms [241], and where a string diagram can be a first-class engineering artefact rather than an illustration [173]. An S-complex trades that line’s schema generality for one graded shape with a semiring parameter; the trade is what makes well-formedness a tensor computation.

This chapter defines the object and its morphisms (section 6.1), tours the instances that choice of  $\mathbb{S}$  buys (section 6.2), states the encoding discipline that decides when a complex is stored versus derived (section 6.3), presents the certified Morse graph as the flagship rank-1 instance with its quantitative refinement (section 6.4), works the string-diagram instance in full — including the reading under which a well-formed hypernet *is* an S-complex (section 6.5) — and closes with a ledger separating definitional content from design directions (section 6.6). Sections 6.1 and 6.4 carry everything the rest of the book consumes; section 6.5 is the most likely to surprise, and a reader with no stake in string diagrams can skip it without loss of continuity.

## 6.1 The definition

Throughout,  $\mathbb{S}$  is an *ordered semiring*: a semiring  $(\mathbb{S}, 0, 1, +, \cdot)$  equipped with a preorder  $\leq$  such that  $0 \leq 1$  and both operations are monotone in each argument. Order-equivalence is derived, not assumed:  $x \cong y \Leftrightarrow x \leq y \wedge y \leq x$ . No subtraction is ever required. That restraint is the point: the instances worth having — Booleans, counts, port sets, min-plus costs — live in semirings that have no subtraction to offer.

A *tensor* over  $\mathbb{S}$  indexed by finite sets  $A_0, \dots, A_{k-1}$  is a finite function  $\prod_{i < k} A_i \rightarrow \mathbb{S}$ , and juxtaposition of tensors denotes contraction over the shared index (sum of products, in  $\mathbb{S}$ ), as in the contraction vocabulary of chapter 12.

**Definition 6.1** (S-complex). An *S-complex* of rank  $r$  consists of finite cell sets  $C_0, C_1, \dots, C_r$  (cells in dimension 0 through  $r$ ) together with, for each  $0 < i \leq r$  and each sign  $e \in \{+, -\}$ , a rank-2 boundary tensor

$$\partial_i^e : C_i \times C_{i-1} \longrightarrow \mathbb{S},$$

satisfying, for each  $1 \leq i \leq r - 1$ , the *sign-split chain condition*

$$\partial_i^+ \partial_{i+1}^+ + \partial_i^- \partial_{i+1}^- \cong \partial_i^- \partial_{i+1}^+ + \partial_i^+ \partial_{i+1}^- : C_{i+1} \times C_{i-1} \rightarrow \mathbb{S}. \quad (6.1)$$

Stated as one dependent type, with  $[N]$  the finite ordinals and  $\text{Fin}$  the concretely finite sets, the presented data of the genus is

$$\sum_{N: \mathbb{N}} \sum_{C: \prod_{n: [N]} \text{Fin}} \prod_{i: [N-1]} \prod_{e: \{+, -\}} [\partial_{i+1}^e: C_{i+1} \times C_i \rightarrow \mathbb{S}]$$

—  $N$  graded levels and a sign-split boundary pair per consecutive pair of levels, nothing else. The type records presentations only; condition (6.1) is a property checked of a presentation rather than a component packaged in it, so one schema serves both the complexes that satisfy it and the raw presentations a checker has not yet admitted. The rank  $r$  of Definition 6.1 is  $N - 1$ .

Condition (6.1) is the classical  $\partial^2 = 0$  with the subtraction moved across the equals sign: over a ring, setting  $\partial = \partial^+ - \partial^-$  and expanding  $\partial_i \partial_{i+1} = 0$  gives precisely “matched sign pairs equal mismatched sign pairs.” Stated this way the condition makes sense over any ordered semiring, and each side is two contractions and a sum, so checking well-formedness of a presented complex is a fixed, small pattern of contraction rows per dimension — the bulk-checkable shape the engine is built around. An elementary instance to hold while reading: a filled square. Each corner lies on two of the four edges, so exactly two routes descend from the 2-cell through an edge to that corner; however the edges are oriented, one route carries matched signs and the other mismatched, so the two sides of (6.1) agree entry by entry — the corner-cancellation of  $\partial^2 = 0$ , surviving with parity where its minus signs used to be. For  $r \leq 1$  the condition is vacuous, and a presentation of a rank-1 complex should say so plainly rather than imply a check that never ran.

The two signs record *combinatorial orientation*: for a directed edge  $a$  from  $x$  to  $y$ , the source incidence lives in  $\partial_1^-(a, x)$  and the target incidence in  $\partial_1^+(a, y)$ . This sign records a property of the diagram itself rather than of any dynamics drawn on it; when a dynamical certificate needs a notion of inward and outward flow across a face, that is separate label data riding on the cells, never a reinterpretation of the boundary signs.

**Definition 6.2** (morphism of S-complexes). Let  $C$  be an  $\mathbb{S}$ -complex and  $D$  a  $\mathbb{T}$ -complex with  $\text{rank}(C) \leq \text{rank}(D)$ . A *morphism*  $f: C \rightarrow D$  consists of a function  $f_i: C_i \rightarrow D_i$  for each dimension  $i$  of  $C$ , regarded semantically as a tensor  $f_i: C_i \times D_i \rightarrow \mathbb{T}$  whose entries are 0 and 1, together with a lax morphism of ordered semirings  $f_S: \mathbb{S} \rightarrow \mathbb{T}$  (monotone,  $f_S(0) \cong 0$ ,  $f_S(1) \cong 1$ ,  $f_S(x + y) \leq f_S(x) + f_S(y)$ , and  $f_S(x \cdot y) \leq f_S(x) \cdot f_S(y)$ ), such that for every dimension  $0 < i \leq \text{rank}(C)$ , every sign  $e$ , and every  $(c, d) \in C_i \times D_{i-1}$ ,

$$\sum_{d' \in D_i} f_i(c, d') \partial_i^{D, e}(d', d) = \sum_{c' \in C_{i-1}} f_S(\partial_i^{C, e}(c, c')) f_{i-1}(c', d). \quad (6.2)$$

Equation (6.2) is the chain-map square, sign by sign: mapping a cell forward and taking its boundary in  $D$  agrees with taking its boundary in  $C$ , pushing the cells forward, and translating the coefficient values through  $f_S$ . Laxity in  $f_S$  is deliberate. The useful coefficient translations are *forgetful* — cardinality (from port witnesses to counts), support (from counts to incidence), and coarse quantitative summaries (from fine margins to dwell bounds) — and translations of the last kind are subadditive rather than exact, so demanding exactness would refuse precisely the summaries the tower is for.

## 6.2 Instances by choice of semiring

The definition specializes by choice of coefficient semiring:

| object                | $\mathbb{S}$          | rank | boundary reading                             |
|-----------------------|-----------------------|------|----------------------------------------------|
| directed graph        | 2 (Booleans)          | 1    | $\partial_1^-$ source, $\partial_1^+$ target |
| directed hypergraph   | $\mathbb{N}$          | 1    | tail/head multiplicities                     |
| cubical complex       | 2                     | $d$  | oriented facet incidence                     |
| oriented graded poset | 2                     | any  | covering relation, one sign each             |
| Lefschetz complex     | a ring's split halves | any  | incidence coefficients                       |
| string diagram        | port names (§6.5)     | 1    | <i>which ports</i> , not just how many       |

*Remark 6.3* (oriented graded posets). Oriented graded posets, a combinatorial substrate of higher-categorical diagram rewriting [104], embed as Boolean complexes in which each covering pair carries exactly one of the two signs. The shape predicates that theory cares about (roundness, molecule-hood, regularity) remain predicates on top of the complex, as that literature states them, with the complex supplying the data they are predicates of.

*Remark 6.4* (Lefschetz complexes). Lefschetz complexes, a combinatorial carrier of Conley-theoretic invariants [183], carry ring coefficients without a ring: a classical incidence coefficient enters as its split halves  $k = k^+ - k^-$ , one sign each, so entries stay in  $\mathbb{N}$  and subtraction never enters the schema.

*Remark 6.5* (the coefficient tower). The coefficient levels form a tower. Cardinality maps a string diagram's witness sets to a directed hypergraph's multiplicities, and Boolean support forgets those to bare incidence. Both maps are lax morphisms in the sense of Definition 6.2 with the identity on cells, so the port, counting, and incidence readings are three resolutions of a single object.

### 6.3 Generators or presentations

Not every complex the toolkit reasons about should be stored as one. The encoding discipline distinguishes two postures.

- **Generator-encoded** where the complex is canonically derivable: grid certificates store grid lines and cell selections, never cell lists or incidence tensors — the cubical complex, with its orientation-split boundary, is recomputed from the generators by every consumer. Skew between a stored presentation and its generators is then unrepresentable rather than checked.
- **S-complex-encoded** where the boundary *is* the content: a Morse graph's edges, a reduced complex, a connection matrix. Here there is no generator to fall back on — the incidence data is precisely what the certificate asserts — so the presentation of Definition 6.1 is the wire object, and condition (6.1) (where non-vacuous) is part of its well-formedness check.

The two postures compose: a quotient from a generator-encoded complex onto an S-complex-encoded one is a morphism in the sense of Definition 6.2, with the derived presentation appearing only transiently on the checking side.

### 6.4 The Morse graph, quantitatively

The global stratum's payload (chapter 14, QMorse row) is a certified Morse graph: finitely many blocks, finitely many directed connections. As data it ships in adjacency dialect (a vertex count and an edge list), and that dialect *is* the rank-1 Boolean S-complex:  $C_0$  the Morse sets,  $C_1$  the connections,  $\partial_1^-$  source,  $\partial_1^+$  target. Acyclicity is the checker's to confirm; the confirmation, in this vocabulary, is an order witness on  $C_0$  of the same kind section 6.5 uses for string diagrams.

The quantitative refinement adds a *labelling* without changing the complex: cells carry values in the ordered semiring  $\text{DWELL} = ([0, \infty], \min, +)$  — the cost quantale of Lawvere's generalized metric spaces [157], whose additive unit is  $\infty$  and whose multiplicative unit is 0, ordered by the reverse of the numerical order, which is what makes  $0 \leq 1$  hold — with connections labelled by certified lower bounds on transit time and Morse sets labelled by their sojourn bounds, which for genuine Morse sets are  $\infty$ . The semiring arithmetic then guards the composite claims against overstatement: min-plus contraction of a path through an intermediate Morse set yields  $\infty$ , so the algebra itself reports that no finite total-time bound through a recurrent set is being asserted, while per-leg bounds stay finite and usable. This is the intended serialization

Figure 6.1: One diagram, three coefficient resolutions. Wire  $y$  feeds both input ports of box  $b$ , so the witness set  $\partial_1^-(b, y)$  holds two singleton port sequences; cardinality forgets *which* ports to *how many*, and Boolean support forgets that to *whether at all* (Remark 6.5). Entries not shown are  $\emptyset$ , 0, 0.

form for the quantitative Morse tier: the graph presented as in Definition 6.1, the rates as cell labels (extended nonnegative rationals in the machine artefact), and the projection from the underlying grid complex onto the Morse graph stated as a morphism — cells to their Morse or transit class, fine certified margins translated laxly to dwell bounds — rather than as an unstated convention between two schemas.

## 6.5 String diagrams: the port semiring

This instance shows why the coefficients form a *semiring parameter* rather than a Boolean convention. Fix a supply  $\mathcal{P}$  of *port names* — opaque identifiers, meaningful only up to renaming. Let  $\mathbb{S}_{\text{port}}$  be the semiring of finite *multisets* of finite sequences over  $\mathcal{P}$ : addition is multiset union with zero  $\emptyset$ , multiplication is elementwise concatenation with unit  $\{\varepsilon\}$ , and the order compares cardinalities — so the derived order-equivalence is blind to the names themselves, which is the renaming-invariance the names’ opacity demands.<sup>1</sup>

A *string diagram* over a signature is a rank-1  $\mathbb{S}_{\text{port}}$ -complex —  $C_0$  the wires,  $C_1$  the boxes — together with a morphism into the complex presenting the signature ( $C_0$  the sorts,  $C_1$  the generators, each generator’s canonical ports as its boundary values). A boundary value  $\partial_1^-(a, x)$  is a *witness set*: one singleton sequence per input port of box  $a$  attached to wire  $x$ , and dually for outputs. Over  $\mathbf{2}$  an edge could only assert incidence; over  $\mathbb{S}_{\text{port}}$  the value says *what flows where* — the difference between a reachability structure and a diagram whose wires carry content comes down, in this vocabulary, to the choice of semiring. The signature morphism does the typing: its cell maps send boxes to generators and wires to sorts, and its coefficient translation  $f_S$  matches each diagram port to the generator port it instantiates, so argument order lives in the signature once instead of in every diagram. Sequence concatenation earns its place under composition, where contracted products accumulate port *paths* witnessing composite incidences; at rank 1 only singletons occur. Figure 6.1 works a two-box example and reads its boundary data at the three coefficient resolutions of Remark 6.5.

Structural conditions on the diagram are then one clause each, and free-structure theorems select which clauses to impose:

| producer/consumer discipline         | acyclicity | free structure presented        |
|--------------------------------------|------------|---------------------------------|
| none                                 | none       | hypergraph category [26]        |
| $\leq 1$ producer, $\leq 1$ consumer | none       | traced symmetric monoidal [137] |
| $\leq 1$ producer, $\leq 1$ consumer | witness    | symmetric monoidal [27]         |
| $\leq 1$ producer, consumers free    | witness    | gs-monoidal [84]                |

Here “ $\leq 1$  producer” is the port-counting condition  $\sum_{a \in C_1} |\partial_1^+(a, x)| \leq 1$  for every wire  $x$ , and dually for consumers — the cardinality order makes counting a first-class operation. The acyclicity witness is a

<sup>1</sup>Multisets rather than sets, for a reason worth checking: concatenation can merge distinct pairs of sequences  $\langle 1 \rangle \cdot \langle 2, 3 \rangle$  and  $\langle 1, 2 \rangle \cdot \langle 3 \rangle$  both concatenate to  $\langle 1, 2, 3 \rangle$ , so two *sets* of equal cardinality can have products of different cardinalities, and multiplication would fail the monotonicity section 6.1 demands of every coefficient semiring. Multisets count collisions instead of merging them, which makes cardinality exactly additive and multiplicative. The witness sets arising in diagrams are unaffected: distinct ports give distinct sequences.

function  $t: C_0 \rightarrow P$  into a poset with  $t(\text{input wire}) < t(\text{output wire})$  across every box: a one-pass check and a rewrite-friendly certificate.

### 6.5.1 Hypernets read as S-complexes

The hypernet of chapter 10 sits in the third row of the table: its linearity condition is producer-and-consumer monogamy and its static-single-assignment order is an acyclicity witness, as that chapter already observes in citing the free-structure correspondence. The reading assembles as follows. Wires are the 0-cells; applications are the 1-cells; an application's ordered input and output lists are the two boundary rows, with list position serving as the port name — the representation takes the renaming quotient so the semiring does not have to. The catalogue plays the signature: the morphism sends each application to its box, each wire to its tensor type, and its coefficient translation records which argument slot each wire fills. Two strata of the hypernet deliberately live *beside* the complex rather than in it: box payloads (constants, contraction patterns, polynomial coefficients) are cell labels, just as rates are labels on the Morse graph; and the interface is a cospan of morphisms from rank-0 complexes — an ordered list of graph inputs and one of graph outputs, each simply a function into  $C_0$ , which is what the declared interface lists already are.

The vocabulary also makes the design space around the interface legible in single clauses. Letting the output leg of the cospan hit any wire — including one an application already consumes — declares a read-out port without touching the inner complex or its monogamy, since the legs were never part of either. If consumer-side monogamy is retired while the producer side is kept, the diagram genus moves one row down the table, to the gs-monoidal discipline of every static-single-assignment compiler representation — def once, use many — with copy and discard absorbed into the wiring. Both are stated here as readings the definition supports rather than as changes made: the shipped hypernet remains the monogamous, acyclic row, and its bytes, digests, and substitution laws are those of chapter 10, unchanged.

## 6.6 Ledger

What in this chapter is what:

- **Definitional.** Definitions 6.1 and 6.2, the derivation of (6.1) from  $\partial^2 = 0$ , the instance table, and the free-structure table (whose correspondences are the cited literature's theorems, not this book's).
- **Machine artefact.** The genus is declared as a standard-library theory of the geolog engine (`theories/SComplex.geolog`), which names this chapter as its expository companion, and the chain condition's contraction factoring is generated from a surface statement of the tensor law (`theories/SComplexGenus.geolog`). The theory is staged design vocabulary, exercised by the engine's tests rather than by production data.
- **Shipped elsewhere in this book.** The Morse-graph payload shape and its checker obligations (chapter 14); the hypernet IR, whose linearity and ordering conditions this chapter's section 6.5.1 re-reads (chapter 10); the contraction machinery that makes condition (6.1) bulk-checkable (chapter 12).
- **Design tense.** The quantitative Morse serialization in complex-plus-labels form and its quotient-as-morphism statement (section 6.4); any S-complex-native storage for hypernets (section 6.5.1 is a reading, and the canonical bytes are unchanged by it); mechanized S-complex morphisms, of which the toolkit currently has none — the Morse quotient is the natural first target. Higher-dimensional rewriting on this substrate (equivalence cells over diagrams) is out of this chapter's scope entirely.

PART II

# QTSL: Quantitative Temporal Specification Logic

---

## Quick Start

---

In this chapter you will produce a machine-checkable certificate of a quantitative claim about a stochastic system, in milliseconds, and see exactly what any checker must re-derive from its bytes. You will meet the three routes by which certificate bytes get checked in this toolkit — and where each route stands at this preview. Then you will break a certificate from the published corpus and watch an exact-arithmetic reader refuse it, with the violated obligation named. The whole loop fits in one sitting; every command is copy-pasteable, and every output shown is the verbatim transcript of a real run — regenerated by the book’s own build, which executes the printed commands and records the tool revisions and run date beside each transcript in the source (one commodity arm64 box; your timings will differ, your bytes will not).

### 7.1 The claim

FrozenLake is Gymnasium’s introductory gridworld: a  $4 \times 4$  frozen lake, sixteen states, four actions, a start square, four holes, one goal. In the *slippery* variant each action moves as intended with probability  $\frac{1}{3}$  and slips to a perpendicular neighbour otherwise, so every trajectory is a random walk biased by the policy, and every reach probability is a rational number whose denominator is a power of three.

The claim to certify: *the recorded policy reaches the goal within ten steps with probability at least*

$$p = \frac{815}{19683} \quad (\text{exactly; } 19683 = 3^9).$$

In QTSL’s vocabulary this is a probabilistic deadline claim,  $\mathbb{P}_{\geq p}[F_{\leq 10} \text{ goal}]$  — the same claim species whose full campaign (deadline ladders, dyadic rounding lanes, a family of environments) the Experiments chapter (chapter 2) re-derives from committed artefacts. One disclosure before we start: 815/19683 happens to be the exact optimum of the ten-step problem, and the producer knows it (it runs an independent floating-point sweep as a cross-instrument), but the certificate below asserts only the lower bound. What a certificate *checks* is always narrower than what its producer *knows*; keeping that line crisp is most of the craft, and the rest of this book is about the vocabulary for widening what is checked.

### 7.2 Setup

Three repositories, cloned side by side. `maitria-coalition/mtk` is the producer toolkit and the only thing you build: a Rust toolchain is its one hard prerequisite, and a GPU is optional throughout (the accelerated lanes load CUDA dynamically and fall back to the same exact host arithmetic — same script, same answers). `maitria-coalition/qtssl-experiments` is the reproduction spine — committed certificates, mutant batteries, receipts — cloned for its bytes; nothing to build. `maitria-coalition/qtssl` is the repository this book ships in: the theories, the machine-checked soundness developments, and the small reference instruments; nothing to build there either — the reader you will run in section 7.5 is dependency-free TypeScript on bare Node  $\geq 22$ .

```
git clone https://github.com/maitria-coalition/mtk
cargo build --release --manifest-path mtk/Cargo.toml
git clone https://github.com/maitria-coalition/qtssl-experiments
git clone https://github.com/maitria-coalition/qtssl
```

## 7.3 Produce

```
$ mtk/target/release/gymdp produce --out out --only frozenlake-4x4
frozenlake-4x4: exact T=100 bound = 0.7441903 [0.005s]
receipts -> out/producer_receipts_rust.json (9 certs, 0 compared, 0 mismatched) [0.005s total]
```

Nine certificates in milliseconds: the exact deadline ladder  $T \in \{5, 10, 25, 50, 100\}$  and a ladder of dyadic-rounded companions. (The 0.7441903 on the log line is a float *rendering* of the  $T=100$  bound, printed for the human reading the log; no float appears inside any certificate.) The document this chapter cares about is the deadline-10 certificate, `out/frozenlake-4x4/exact_T10.cbor`: 2,511 canonical bytes carrying the claim, the transition kernel as 148 rows of exact rationals, the recorded policy, and the eleven-by-sixteen value table — the complete witness data from which everything asserted can be re-derived by something that has never met the producer. It is also, byte for byte, the artefact committed in the experiments repository (sha256 prefix 66040e59, either way — compare against `qtsl-experiments/gymnasium/out/frozenlake-4x4/`). In this toolkit “reproduces the published artefact” is a statement about equality of bytes, not about agreement to some tolerance — which is what lets a checker’s verdict on the committed corpus and on your fresh production be the same fact.

One vocabulary correction before anyone checks anything, because the file extension just lied to you: this toolkit has no certificate file format. In the shipped architecture a certificate is ordinary database content — rows of a signed, content-addressed geolog commit, carried on the same rails as every other fact the system stores (the Executive Summary’s one-set-of-bytes, three-consumers stance — chapter 1; the Geolog part of this book is that database’s own manual). The theory defining those rows is in this repository, as `data: theories/Qtsl.geolog`, with its drift-alarmed battery beside it. The sidecar file you just wrote is the producer’s local carriage for that content — and the reproduction spine already commits this family both ways: the sidecar artefacts, and the same certificates sealed as rows of signed geolog commits in a `g1c/` directory beside them, with content identity between the two forms re-proven at every production. What survives every carriage is the standard the content answers to: a self-contained document of exact numbers, complete enough to re-derive every obligation, with no side channel to consult. You will read a certificate directly as rows, in plain text, two sections from now.

## 7.4 What a checker re-derives — and who checks

Any checker of this certificate, by any route, re-derives four obligation families from the document alone, in exact rational arithmetic:

- *well-formedness* — kernel probabilities lie in  $[0, 1]$  and sum to one per state–action pair; indices are in range;
- *boundary* — the value table’s final row vanishes off the goal set;
- *step* — each table entry is dominated by its expected successor value under the recorded policy’s action,  $V_t(s) \leq \mathbb{E}[V_{t+1}]$ ;
- *claim* —  $p \leq V_0(\text{init})$ .

Chained, these force the table to be a genuine under-approximation of the reach probability, so the claim follows from the bytes alone. Nothing the producer computed is taken on trust; the producer’s speed lives entirely upstream of the certificate. This division — fast untrusted search, small independent replay — is the toolkit’s organizing principle, and it is why the producer is allowed to be a GPU-accelerated, float-assisted, LLM-advised anything: a wrong producer costs a rejected certificate, never a false verdict.

Who does the re-deriving is a deliberately plural answer: one set of bytes, three consumers, each trading speed against the size of what you must trust (the Executive Summary carries the full stance). Their standing for *this* certificate, dated to this preview:

- *The geolog engine* — the fast path: certificate rows chased, monitored, and enforced like any other rows; engineering-grade assurance, deliberately no mechanized soundness story. This certificate’s row form — one sealed commit carrying the system, the specification, the judgment, and the proof content — is committed in the reproduction spine beside the sidecar artefacts, and the fast-path

checker re-verifies all four obligation families from the sealed rows alone: one make target re-checks the family's containers against their manifest, expected verdicts included, and the Experiments chapter's timing tables carry the fast-path column from real runs.

- *qtslab* — the certified checker: a standalone binary whose end-to-end soundness theorem (machine-checked in HOL4, grounded through the CakeML verified compiler in the Arm instruction set's semantics) says that if it prints ACCEPT on a claim followed by an arbitrary stream of bytes, the claim is semantically true. Precisely: acceptance binds to validity of the accepted sequent under every admissible valuation of the hypernet the certificate itself declares (chapter 10) — the Bernstein Logic fragment, which is all its input format carries today; a certificate reaching beyond that fragment is refused, not silently accepted (the Executive Summary is explicit about the scope: the boundary is *qtslab*'s, not the row vocabulary's). A demonstrated route, assembling now: the same compiler-and-theorem recipe has already carried a complete predecessor checker to a machine-code soundness theorem on real hardware — and that proven chain, re-run on its native ISA during this chapter's verification campaign, verified campaign fixtures in single-digit seconds each and refused all six mutants put to it.
- *The Lean route* — the same bytes reconstructed as a theorem inside Lean's kernel, by reflection; expected to be too slow for machine-scale certificates, and kept in the roster to *measure* that rather than assert it. It has been measured, twice, across two certificate-format generations: the Experiments chapter carries the scaling law, the admission gate fitted to it, and the expectation confirmed with its boundary stated.

No transcript in this section, on purpose: for the certified and Lean routes, printing one would mean pretending they are further along for this family than they are, and a book whose subject is checkable evidence does not get to fake its own. The fast path is runnable today — the reproduction spine's make target re-checks this family's committed containers, mutant battery included, whenever you like. The checking you can run *and read whole* is the next section's, on a certificate family whose rows are committed as plain text.

## 7.5 Break one

A checker that cannot say *no* teaches nothing. The FrozenLake family's sealed rows come with a committed mutant battery of their own, but a sealed container is built for checkers' eyes; the published-table campaign additionally stores its certificates as plain-text row listings you can open and read — so we break one of those, and the lesson transfers intact.

That campaign (section 2.3 of chapter 2) re-derived a peer-reviewed neural-certificate results table in exact arithmetic, and *faulty\_uniform* is its most instructive row: the one whose exact two-sided bracket showed a published “sound” bound to be no bound at all. Its upper-bound certificate is committed as rows in the reference listing notation — plain text you can open:

```
$ cd qtsl-experiments/supermartingales/out/sec3
$ sed -n '62p' certs/faulty_uniform/bound.rows.txt
op[ 59] funa fun=G<stack/TConst> args=[q:16524448999/8406920828251] value=L58
```

One hundred and twelve rows like this one — sorts, exact simplex coordinates, Bernstein coefficients, and the proof structure that cites them — resolving their names against pinned theory listings. Beside the corpus, the book's own repository carries a reference reader and checker for this certificate family: three TypeScript files, zero dependencies, readable in an afternoon (*qtsl/checkers/supermartingales*). Point it at the certificate, and at the campaign's committed mutant of the same certificate:

```
$ CHK=../../../../qtsl/checkers/supermartingales
$ node --experimental-strip-types $CHK/check_rows.ts \
  --stack $CHK/theories/BLstack.rows.txt --cert $CHK/theories/BLCert.rows.txt \
  certs/faulty_uniform/bound.rows.txt mutants/faulty_uniform/M1_false_bound.rows.txt
ACCEPT certs/faulty_uniform/bound.rows.txt proof_nodes=3
REJECT mutants/faulty_uniform/M1_false_bound.rows.txt berncone.coeff
```

Now break it yourself. The certificate survives a coefficient perturbed in the sound direction — slack is real, and the checker is not grading effort — so nudge the coefficient you just looked at the *other* way, by

exactly 1/8,406,920,828,251:

```
$ sed 's|448999|449000|' certs/faulty_uniform/bound.rows.txt > my_broken.rows.txt
$ node --experimental-strip-types $CHK/check_rows.ts \
  --stack $CHK/theories/BLstack.rows.txt --cert $CHK/theories/BLCert.rows.txt \
  my_broken.rows.txt
REJECT my_broken.rows.txt berncone.coeff
```

Two things to notice. The refusal is *witness-shaped*: the identifier names the violated obligation family (membership of the certificate polynomial’s Bernstein coefficients in the claimed cone), and the checker’s failure record beneath it carries the offending coefficient’s index and exact value, because failure geometry is routing advice for whoever must repair the certificate. And the committed mutant battery is the checker’s obligation list made executable — the battery, not the prose, gives the operational statement of what an ACCEPT means (the Cookbook develops this discipline as a pattern: section 19.3 of chapter 19).

One label, to keep the trust story crisp: the program you just ran is a *reference instrument* — the reproduction spine’s own exactness oracle, differentially pinned against an independent implementation across the campaign corpus and its mutant battery — and deliberately *not* one of the three checking routes. Its job is to make “the battery must refuse” an executable fact, and to let you watch obligations re-derived from rows alone through code small enough to read whole. When the stakes are real, the same rows go to the routes of section 7.4.

## 7.6 The same loop from TypeScript

The producer toolkit’s TypeScript surface, @maitria/mtk, ships as the ts/ package of the maitria-coalition/mtk repository (napi bindings over the same Rust core — there is one implementation of every construction, and TypeScript reaches it in-process). The shipped install route is the checkout you already have from section 7.2 — it requires a Rust toolchain, because the native addon builds from source:

```
cd mtk/ts && npm install && npm run build:native # Rust toolchain required
cd ~/your-project && npm install ../mtk/ts # npm links the package
```

(@maitria/mtk on the npm registry: arriving; the checkout path above is the shipped route at this preview.) Node ≥ 22.18 throughout — the package’s declared engines floor. The producing half of the loop again, this time constructing the certificate yourself — and building the mutant with your own hands:

```
// quickstart.ts – produce the FrozenLake certificate, then break it.
import { writeFileSync } from "node:fs";
import { dp } from "@maitria/mtk";

// The environment: Gymnasium's FrozenLake-4x4, slippery (success rate 1/3).
const model = dp.frozenlake("4x4", true, "1/3");

// The claim: exact finite-horizon dynamic programming to deadline T = 10.
const res = model.exact(10);
console.log("claim:", res.bound);

// Emit the certificate: canonical bytes, encoded by the Rust core.
const meta = {
  envId: "FrozenLake-v1",
  mdpName: "frozenlake-4x4",
  repoSha: dp.gymSha(),
  kwargs: "",
};
const bytes = res.emit(meta);
writeFileSync("exact_T10.cbor", bytes);
console.log("wrote exact_T10.cbor:", bytes.length, "bytes");

// Now break it: raise one interior value-table entry to 1.
// (docMutate refuses unless the unmodified doc round-trips byte-identically.)
const broken = dp.docMutate(bytes, [
  { path: ["table", 1, 0, 0], setHex: "01" },
```

```

    { path: ["table", 1, 0, 1], setHex: "01" },
  });
writeFileSync("mutant_table_raised.cbor", broken);
console.log("wrote mutant_table_raised.cbor:", broken.length, "bytes");

$ npx tsx quickstart.ts
claim: 815/19683
wrote exact_T10.cbor: 2511 bytes
wrote mutant_table_raised.cbor: 2509 bytes

```

The bytes you just constructed are byte-identical to the ones `gymdp` emitted in section 7.3, and therefore to the committed corpus artefact — the same `sha256`, all three ways. And you now hold what the mutant-battery discipline calls a matched pair: golden bytes, and a variant broken in precisely one field (the mutation seam checks that the unmodified document round-trips byte-identically before it will perform surgery, so your mutant differs from the golden bytes exactly where you aimed). The corpus commits this family's battery beside the artefacts, expected verdicts in the receipts — and the sealed row form carries a second battery of thirteen row-form mutants, each one's expected verdict and violated obligation named in its manifest. You already know from section 7.5 what a refusal at the row level looks like.

## 7.7 What you just did, and where it goes

You ran the trust architecture of this book once, in miniature: an untrusted producer constructed complete witness data fast, and reproduced a published artefact to the byte; you read the obligations a checker must re-derive, and the current state of the three routes that re-derive them; and on the published corpus you watched an exact-arithmetic reader accept a certificate stored as rows and refuse its mutants — including yours — with the violated obligation named. Three widenings from here:

- *Producing for real.* The Tutorial (chapter 8) teaches the producer's craft on the TypeScript surface: exactness as a type property, propose-then-dispose, specs and judgments, derivation rows from the Rule Catalogue, and refusal-driven iteration.
- *Richer claims.* Deadline reachability is one species. The Rule Catalogue (chapter 15) is the full inventory of certified inference; the fabrication-line worked example (chapter 17) runs the stack over a model with batching, failures, and re-entrant flow.
- *Graded checking, priced.* The three routes of section 7.4 are not interchangeable, and the Experiments chapter's design keeps their price differences public: three wall-clocks per experiment — produce, check-fast, check-certified — each measured on its route's native substrate, so the cost of each grade of assurance stays a published number rather than a promise.

# Tutorial: Producing Proofs with MTK

---

The Quick Start (chapter 7) had you run one producer end to end. This tutorial teaches you to *be* one: to construct specifications, judgments, and derivation rows with the producer toolkit’s TypeScript surface, to read refusals as instructions, and to leave behind artefacts an independent checker will accept. The intended reader is either a capable agent doing verification work or a verification-literate human; the text is written for the human, and the agent will cope. Every listing below runs as printed, and every output shown is the verbatim transcript of a real run: the book’s build regenerates these transcripts by executing the printed listings, and each one’s source records the exact tool revision and date it ran (one commodity arm64 box).

## 8.1 The producer’s stance

Three commitments shape every surface you are about to touch, and every signature below answers to one of them:

1. *Nothing here is trusted.* No function in the producer toolkit renders a verdict anyone should believe. Validation helpers exist — they save round-trips — but they are preflights; the checker’s independent replay of your artefact is the only authority. A wrong producer costs a rejected certificate, never a false verdict, which is why the producer is allowed to be fast, heuristic, and as clever as it likes.
2. *Witnesses always, never bare verdicts.* Any operation that can fail for a content reason returns the geometry of the failure — which coefficient, which cell, which field, which subformula — because failure geometry is routing advice for your next attempt. You will spend much of your producing life reading refusals; the API is designed so that this is pleasant.
3. *Exactness is a type property, not a discipline.* Data that certificates cite is exact — arbitrary-precision rationals and integers — and lives in types that say so. Floating-point data proposes and routes but cannot cross into the exact world by accident: the one bridge is an explicit snap, and what comes out of it is a new proposal to certify, not a blessed float.

## 8.2 Setup

The TypeScript package `@maitria/mtk` lives in the `maitria-coalition/mtk` repository as its `ts/` package over a native addon crate (the front matter’s preview note applies to the package’s migration state at this preview). It is two layers by design: a deliberately flat native boundary (napi bindings over the Rust core — there is exactly one implementation of every construction, and it is the Rust one; the differential receipts shipped with each binding prove the TypeScript-driven path emits bytes identical to the Rust-driven one) and an *arrangement* layer that owns all public idiom — discriminated unions, branded types, readonly records. You will only ever touch the arrangement.

```
git clone https://github.com/maitria-coalition/mtk
cd mtk/ts && npm install
npm run build:native # cargo builds the addon; CUDA optional, loaded at runtime
```

A Rust toolchain is required — the native addon builds from source. To use the package from your own project, install it by path (`npm install ../mtk/ts`; `npm` links the checkout), which is the shipped route at this preview; `@maitria/mtk` on the npm registry: arriving. Node  $\geq 22.18$  (the package’s declared engines floor); producer scripts run under `npx tsx` with no build step of their own. Boxes without a GPU run the same scripts and get the same answers — acceleration changes wall-clock, never content.

## 8.3 Exact numbers, and the one bridge from float

The class the certificates cite is `Q`: immutable, bigint-backed exact rationals with a canonical text form "`n/d`". Everything about its API enforces stance 3:

```
// exactness.ts – class-E data is Q; number never crosses the boundary.
import { Q, lp } from "@maitria/mtk";

console.log(Q.from("0.1").add("0.2").toString());           // exact decimal parse
console.log(Q.from("-2.04e-2").toString());                 // scientific, exact
console.log(Q.of(815, 19683).sub(Q.of(1, 27)).toString());

try {
  Q.from(0.1);                                              // refused: ambiguous
} catch (e) {
  console.log((e as Error).message);
}

// The one bridge from float to exact: an explicit snap. The snapped
// value is a new PROPOSAL to certify, never a blessed float.
console.log(lp.rationalize(0.3333333333333333, 1000).toString());
console.log(lp.rationalize(Math.PI, 1000).toString());

$ npx tsx exactness.ts
3/10
-51/2500
86/19683
Q.from(0.1): non-integer numbers are ambiguous – pass "n/d" text, a bigint, or Q.of(n, d)
1/3
355/113
```

Decimal *text* parses exactly (`"0.1"`  $\mapsto$   $1/10$ : the string denotes a rational, unambiguously), but the *double* `0.1` is refused — it denotes  $3602879701896397/2^{55}$ , and pretending otherwise is how exactness-as-discipline projects fail. When you genuinely hold a float and want a rational, you say so: `rationalize` snaps to the best approximation under an explicit denominator budget (note  $\pi \mapsto 355/113$ , as it should). The budget is a knob you will meet again: coarser snaps make smaller, cheaper-to-check certificates, and no snap can make a false claim true — the checker decides either way.

## 8.4 A first certified fact

The smallest genuinely useful certified fact in this toolkit: the sign of a polynomial on a region. Bernstein coefficients of  $p$  over a simplex bound  $p$  there, so an all-positive coefficient table *is* a sign certificate — data whose correctness an independent checker re-derives by arithmetic alone, no cleverness required.

```
// sign.ts – certify the sign of a polynomial on cells of a triangle.
import { Q, poly } from "@maitria/mtk";

// p(x, y) = x^2 + x*y - y + 1/3
const p: poly.Term[] = [
  { exps: [2, 0], coeff: 1 },
  { exps: [1, 1], coeff: 1 },
  { exps: [0, 1], coeff: -1 },
  { exps: [0, 0], coeff: Q.of(1, 3) },
];

// the unit triangle, split at the midpoint of its hypotenuse
const mid = [Q.of(1, 2), Q.of(1, 2)];
const t = poly.simplexBern({
  poly: p,
  cells: [
    [[0, 0], [1, 0], mid],
  ],
});
```

```

    [[0, 0], mid, [0, 1]],
  ],
  degree: 4, // elevate past deg(p): tighter enclosures
  device: "cpu", // pin the host rung: same integers on any box
});

console.log(`ran on ${t.device}; ladder served F/M/host = ${t.served}`);
for (let b = 0; b < t.cells; b++) {
  const [lo, hi] = t.enclosure(b);
  const verdict =
    lo.sign() > 0 ? "p > 0 CERTIFIED"
    : hi.sign() < 0 ? "p < 0 CERTIFIED"
    : "sign open (subdivide)";
  console.log(`cell ${b}: p in [${lo}, ${hi}] - ${verdict}`);
}

$ npx tsx sign.ts
ran on cpu(hostref); ladder served F/M/host = 0,0,2
cell 0: p in [1/6, 4/3] - p > 0 CERTIFIED
cell 1: p in [-2/3, 1/3] - sign open (subdivide)

```

Read the first line closely, because it is stance 3 at work in the machinery. The enclosure pipeline is exact end to end — integer numerators over a shared per-cell denominator — and it runs as a *precision ladder*: fixed-width device tiers serve the cells they can handle without overflow, and any cell they cannot is flagged and re-derived by an arbitrary-precision host replay. Every rung computes the same exact integers; the ladder trades width for speed, never exactness for speed. The listing pins device: "cpu" so that both cells are served by the host rung (0,0,2) and your transcript matches this one on any box, GPU or none; drop the pin (the default is "auto") and a free GPU takes the cells instead — on this box the package's own example reported `cuda:NVIDIA GB10 ... ladder served F/M/host = 2,0,0`. Same cells, same enclosures, same certificate — the transcript differs only in who did the arithmetic.

Cell 1 is the more instructive half of the output: the enclosure straddles zero, so the honest answer is *sign open*, with subdivision as the routing advice. Bernstein enclosures converge under subdivision and degree elevation, so "open" is an invitation to spend more, not a dead end — and when the budget runs out before the sign closes, that too can be certified rather than shrugged (the Cookbook's honest-stop pattern, section 19.2 of chapter 19).

## 8.5 Propose, then dispose

The two-tier discipline in one screen: a linear program solved twice, once by the float lane (fast, unciteable), once by the exact lane (the only tier a certificate may cite).

```

// two-tier.ts – the float lane proposes; the exact lane disposes.
import { lp } from "@maitria/mtk";

// minimize x0 + x1 subject to x0 + 2*x1 = 1, 3*x0 + x1 = 1, x >= 0
const cols = [{ cost: 1 }, { cost: 1 }];
const rows = [
  { lo: 1, hi: 1, cols: [0, 1], coefs: [1, 2] },
  { lo: 1, hi: 1, cols: [0, 1], coefs: [3, 1] },
];

// tier F: HiGHS, floats – fast, unciteable; duals are routing advice
const f = lp.floatSolve(cols, rows);
console.log("float:", f.status, f.objective, "duals", f.rowDuals);

// tier E: exact Bland simplex over Q – the only tier a certificate cites
const e = lp.simplexMin([1, 1], [[1, 2], [3, 1]], [1, 1]);
if (e.status === "opt") {
  const at = e.x.map(String).join(", ");
  console.log("exact:", e.value.toString(), "at x =", at);
}

```

```

    }

    $ npx tsx two-tier.ts
    float: optimal 0.6000000000000001 duals [ 0.4, 0.2 ]
    exact: 3/5 at x = 1/5, 2/5

```

The float tier even performs its own indictment: it reports `0.6000000000000001` for a quantity that is  $3/5$ . On a toy problem the exact tier could simply run alone; the discipline earns its keep at scale, where the float lane's job is to find *which* exact computation is worth paying for — its duals say which constraints bind, its solution says where to warm-start, its speed lets you sweep a thousand candidates to find the one worth certifying. The full pattern, with the case studies that shaped it, is the Cookbook's opening chapter (section 19.1 of chapter 19).

## 8.6 Stating claims: specs and judgments

So far we have certified facts the toolkit already knew how to phrase. To produce proofs *about systems*, you state the claim yourself, in QTS: a specification is a record of claim components — each a formula over a system's observables — and a judgment is the record that pairs a specification with a system (or a region, or a pair of specifications — one record species per judgment kind). Both are constructed here as plain data, preflighted in Rust, and emitted as versioned artefacts through the same canon encoder that carries every other certificate.

The Quick Start's FrozenLake claim, stated properly this time:

```

// spec.ts – state the FrozenLake claim species as a specification.
import { spec } from "@maitria/mtk";

// One observable (width 1); the goal region is { x >= 15 }.
const x = spec.unwrap(spec.polyVar(0, 1));
const goal = spec.polyGe(15, x);

// P_{>= 815/19683} [ F_{<=10} goal ] – reach the goal within 10 steps:
// a safety-face component (SProbGE) in the record's forall list.
const phi = spec.probGe("815/19683", spec.deadline(10, goal));

const record = spec.unwrap(spec.build({ name: "reach-goal-by-10", forall: [phi] }));
const artifact = spec.unwrap(spec.encode(record));
console.log(artifact.schema, "-", artifact.bytes.length, "bytes");

// Round-trip: decoded data is data – re-validate before trusting it.
const back = spec.unwrap(spec.decode(artifact.bytes));
console.log("decoded:", back.spec.name, "v =", back.v);

// Now ask for probability 3/2 and let the preflight refuse.
const bad = spec.probGe("3/2", spec.deadline(10, goal));
const r = spec.preflightForall(bad);
if (!r.ok) {
  console.log("refused:", r.refusal.kind);
  if (r.refusal.kind === "probRange")
    console.log(` at ${r.refusal.at.text}: p = ${r.refusal.p}, outside (0, 1]`);
}

$ npx tsx spec.ts
maitria.qtsl.spec.v1 - 179 bytes
decoded: reach-goal-by-10 v = 0
refused: probRange
  at (root): p = 3/2, outside (0, 1]

```

Three habits to take from one screen. First, the wire is visible and versioned: every emitted artefact carries a schema string (`maitria.qtsl.spec.v1`) and a version, and the bytes are produced by the Rust canon encoder — TypeScript never re-implements an encoding, which is why cross-language byte drift is structurally unrepresentable rather than tested away. Second, decoded data is data: decode gives you back

a record, and if you received the bytes from someone else you re-run `build` before leaning on it. Third, the refusal: it is a discriminated value (`kind: "probRange"`), it carries the address of the offence inside the formula tree (`((root) — addresses are relative to the node you preflighted, and record-level checks come with full paths like forall[0].prob.path), and it carries the offending exact value as canonical text (p: "3/2"). Producer code branches on refusal kinds the way it branches on any other data; nothing is buried in exception strings.`

Judgments follow the same grammar one level up: the judgment namespace has one builder per judgment kind — satisfaction, region satisfaction, spec equivalence, distance, and the rest — each taking branded citation handles rather than loose strings, each emitting a versioned artefact. The claim record is deliberately boring; the interesting objects are the derivations that discharge it, which is where the rules come in.

## 8.7 Derivation rows: the Rule Catalogue as an API

Every inference rule in the Rule Catalogue (chapter 15) is available as a typed row builder: premises as typed citations, payload fields exact, side conditions enforced at construction, canonical bytes out. A proof, in this toolkit, is a table of such rows — which is what lets a checker replay it row by row, and what lets a database engine store, merge, and re-derive it like any other data.

The smallest interesting rule is a good first row. `QUnionBound` takes two exception-mass bounds and concludes their sum — the workhorse glue for assembling per-obligation failure budgets into a system-level one:

```
// rule-row.ts – a Rule Catalogue row: cite premises, get the conclusion.
import { rules } from "@maitria/mtk";
const { qtslCore } = rules;

// QUnionBound: from two exception-mass bounds, conclude their sum.
const row = qtslCore.unionBound({
  e1: qtslCore.judgmentRef("qregionsat", 0), // typed premise citations
  e2: qtslCore.judgmentRef("qregionsat", 1),
  a: "1/8",
  b: "1/16",
});
if (row.ok) {
  console.log(row.value.schema, "-", row.value.cbor.length, "bytes");
  console.log("concluded bound:", row.value.bound.toString());
}

// A negative mass is refused with the witness attached.
const bad = qtslCore.unionBound({
  e1: qtslCore.judgmentRef("qregionsat", 0),
  e2: qtslCore.judgmentRef("qregionsat", 1),
  a: "-1/8",
  b: "1/16",
});
if (!bad.ok) {
  console.log("refused:", bad.refusal.kind);
  console.log(" " + bad.refusal.message);
}

$ npx tsx rule-row.ts
maitria.qtsl.union_bound.v0 - 58 bytes
concluded bound: 3/16
refused: signConstraint
QUnionBound.a: sign/range constraint violated by -1/8
```

Notice who computed `3/16`: not this script. Derived conclusions come back from the Rust core's own concludes logic, so the row you emit and the arithmetic it claims were produced by the same implementation the differential receipts pin — your script assembles and cites, it never does load-bearing arithmetic. Notice also the premise handles: `judgmentRef("qregionsat", i)` is a branded type, and a rule whose premise slot

wants a region-satisfaction judgment will not accept a plain number, a proof reference, or a judgment of the wrong kind. The edge discipline of the proof calculus is enforced by the type checker before the checker ever sees your bytes.

When you need more than glue — safety batteries, deadline batteries, Streett bundles, Morse decompositions, composition rules — the pattern never changes: find the rule in the Rule Catalogue, which documents its premises, payload, and side conditions alongside its mechanization status; call its builder; read refusals until the row constructs. The catalogue chapter is the map and stays the map; this tutorial deliberately teaches only the door.

## 8.8 Certificates are documents: read one

The Quick Start ended by mutating a certificate through the generic document seam. Here is the reading half of that seam, on the same bytes — because the fastest way to understand what a checker re-derives is to look at what the producer actually wrote down:

```
// anatomy.ts — a certificate is a document; read it before you trust it.
import { readFileSync } from "node:fs";
import { dp } from "@maitria/mtk";

const bytes = readFileSync("exact_T10.cbor");
const doc = dp.docJson(bytes, []) as Record<string, unknown>;
console.log("fields:", Object.keys(doc).join(" "));
console.log("deadline:", dp.docJson(bytes, ["deadline"]),
  " states:", dp.docJson(bytes, ["ns"]),
  " goal:", dp.docJson(bytes, ["goal"]));
console.log("claim:", dp.docJson(bytes, ["claim"])); // bignum pair, hex
console.log("kernel[0]:", dp.docJson(bytes, ["kernel", 0])); // s a s' p_num p_den

$ npx tsx anatomy.ts
fields: claim deadline env_id goal init kernel kwargs lane mdp_name ns policy repo_sha table v
deadline: 10 states: 16 goal: [ 15 ]
claim: [ '0x032f', '0x4ce3' ]
kernel[0]: [ 0, 0, 0, '0x02', '0x03' ]
```

Everything a checker of this certificate must re-derive — the Quick Start's four obligation families — is visibly *here*: the claim ( $0x032f/0x4ce3 = 815/19683$ ), the kernel as exact rationals (the first row: from state 0 under action 0, probability  $2/3$  of staying put — two of its three equally likely moves bounce off the corner), the policy, the value table. A certificate contains no argument and no trust requests; it contains the numbers that make the argument checkable. When you produce a new certificate species, this is the standard to hold your bytes to: could a stranger's checker re-derive every obligation from the document alone?

That standard is what survives every carriage the document rides. These particular bytes travel as a sidecar file; the reproduction spine commits the same certificate a second way, as rows of a signed, content-addressed geolog commit — ordinary database content whose row vocabulary is `theories/Qts1.geolog` in this repository, with no certificate file format of its own — and you have already read certificate rows directly, as plain text, in the Quick Start's break-it section. What the generic document seam gives you here is the producer-side reading of the content in its canonical byte carriage; the anatomy lesson is identical on either, because completeness reads the same from any carriage.

The mutation seam (`dp.docMutate`) is the same document surface pointed the other way, and it exists because a mutant battery is part of a certificate lane's deliverable, not an optional extra: every claim species ships with mutants its checker must refuse, and a witness that stays green when the claim is broken was never a witness (section 19.3 of chapter 19). The seam checks that the unmodified document round-trips byte-identically before it will perform surgery, so your mutants differ from the golden bytes in precisely the field you broke.

## 8.9 The shape of a real producer program

Scale the last five sections up and you have the actual production programs behind the Experiments chapter. The FrozenLake producer you ran in the Quick Start is a few hundred lines organized along this tutorial's spine, and reading it (the gymdp producer in the `maitria-coalition/mtk` repository, with its receipts and companion drivers in `maitria-coalition/qtsl-experiments`) is the recommended next hour. The anatomy the campaign's producers share:

- *a configuration grid*, not a one-off — environments  $\times$  deadlines  $\times$  rounding budgets, because certificates are cheap once the lane exists and ladders are how cost curves get published;
- *an independent cross-instrument* — a plain floating-point value sweep, kept structurally separate from the exact lane, with an explicit agreement tolerance; it certifies nothing, and it catches producer bugs before any checker has to;
- *exact dominance assertions between lanes* — each dyadic-rounded certificate is checked against its exact sibling ( $0 \leq \text{exact} - \text{dyadic} \leq T \cdot 2^{-k}$ , the gymdp source's own *exact dominance* assertion), so even the cheap lane's error is a theorem, not a hope;
- *emission through the canon encoder, then the mutant battery, then receipts* — machine-readable production receipts (bounds, byte counts, timings, mutant verdicts) written beside the artefacts, because a reproduction spine is built from receipts, not recollections.

When a step refuses mid-program, the refusal's geometry picks the escalation: subdivide the cell, raise the degree, spend a bigger denominator budget, climb from the closed form to the LP to the heavier rule — cheapest instrument first, and certify the honest stop when the budget genuinely ends (sections 19.5 and 19.2 of chapter 19).

## 8.10 Working an obligation workspace

Everything so far drove the toolkit imperatively: your script decided each call, held the intermediate state in variables, and threw both away on exit. That is the right shape for a five-minute production and the wrong shape for one that runs long enough to be interrupted, plays several instruments against one claim, or is worked by something other than its author. The toolkit's session surface exists for that regime. Its bookkeeping object is the *obligation workspace*, and its vocabulary is four nouns:

- an *obligation* is a claim to be certified — a statement of a registered claim kind — with a status: open, discharged, or refuted;
- a *move* is one typed action from the obligation's menu. The menu is the claim kind's to offer: each move declares its parameter schema, a cost hint (cheap to expensive — advice for sequencing, never a gate), and what it may do: discharge, refute, or spawn;
- an *attempt* is one executed move: the outcome, the wall time, and either a *witness* (for discharged or refuted — the exact-tier artefact that justifies the verdict) or *evidence* (for inconclusive — failure geometry, which by now you know to read as routing advice);
- the *event log* is the whole truth: the workspace is a pure fold of an append-only event list, so replaying the log reconstructs the state without re-running any kernel.

Two disciplines are enforced by the workspace itself rather than requested of its users. First, stance 2 is mechanized at the recording boundary: a claim kind that returns a verdict without a witness is refused on the spot — the workspace will not record a bare verdict, so its bookkeeping can never get ahead of the artefacts that justify it. Second, structural moves *spawn*: a decomposition move creates child obligations that jointly cover the parent's claim, and from that moment the parent's status is nobody's to set — it closes only by propagation. All children discharged closes the parent (via `children`); one refuted child refutes it, since the child covers part of the claim. You work the leaves; the workspace does the lifting.

Here is the whole model in one sitting, on a claim small enough to watch:  $x(1 - x) - 1/4 \leq 0$  on  $[0, 1]$  — true, with equality at  $x = 1/2$ . (The package is `@maitria/mtk-session`, the `maitria-coalition/mtk`

repository's session/ package, beside the producer package; install it by path like the producer package in section 8.2. It runs its TypeScript sources directly — Node  $\geq 22.18$ .)

```
// session.ts – work an obligation workspace by hand: you are the strategy.
import { Workspace, polyKind } from "@maitria/mtk-session";

// The claim:  $x(1-x) - 1/4 \leq 0$  on  $[0, 1]$  – true, with equality at  $x = 1/2$ .
const ws = new Workspace([polyKind]);
const root = ws.pose({
  kind: "poly.nonpositive",
  poly: [
    { exps: [2], coeff: "-1" },
    { exps: [1], coeff: "1" },
    { exps: [0], coeff: "-1/4" },
  ],
  box: [["0", "1"]],
});
console.log(`${root.id}: ${ws.describe(root.id)}`);
console.log("menu:", ws.moves(root.id).map((m) => `${m.name}/${m.cost}`).join(" "));

// Cheapest first: one exact Bernstein enclosure of p over the whole box.
const r1 = ws.apply(root.id, "range");
console.log("range:", r1.attempt.outcome, JSON.stringify(r1.attempt.evidence));
console.log(" note:", r1.attempt.note);

// The enclosure straddles zero because p touches it at 1/2. Split there.
const r2 = ws.apply(root.id, "split", { axis: 0, at: "1/2" });
console.log("split:", r2.attempt.outcome, "->", r2.spawned.map((c) => c.id).join(", "));

// The parent is now out of our hands – the workspace says so:
try {
  ws.apply(root.id, "range");
} catch (e) {
  console.log("refused:", (e as Error).message);
}

// Work the leaves; each half certifies by one enclosure.
for (const child of r2.spawned) {
  const r = ws.apply(child.id, "range");
  console.log(`${child.id} range:`, r.attempt.outcome, JSON.stringify(r.attempt.witness));
}

// Nobody set the parent's status; the second discharge propagated it.
const done = ws.get(root.id);
console.log(`${root.id}: ${done.status} (via ${done.via})`, JSON.stringify(done.witness));

// The workspace is a fold of its event log: replay rebuilds it exactly.
const replica = Workspace.replay(ws.events, [polyKind]);
const same = JSON.stringify(replica.snapshot()) === JSON.stringify(ws.snapshot());
console.log("replayed", replica.events.length, "events; state identical:", same);

$ npx tsx session.ts
ob1: (-1)*x^2 + (1)*x + (-1/4) <= 0 on [0, 1]
menu: range/cheap probe/cheap split/cheap search/expensive
range: inconclusive {"enclosure":["-1/4","1/4"]}
note: enclosure straddles 0; split, search, or probe near the suspected maximum
split: spawned -> ob2, ob3
refused: ob1 has open children; work the leaves (its status resolves by propagation)
ob2 range: discharged {"enclosure":["-1/4","0"]}
ob3 range: discharged {"enclosure":["-1/4","0"]}
ob1: discharged (via children) {"dischargedChildren":["ob2","ob3"]}
replayed 5 events; state identical: true
```

Four things in this transcript repay a close look.

*The straddle is real.* The enclosure on the whole box is  $[-1/4, 1/4]$ : the control polygon of a strictly concave parabola lies above it, so the degree-2 ceiling lands at  $1/4$  rather than at the true maximum 0. The note beside the evidence says what to do about it, and the interesting word in it is *where*: “near the suspected maximum.”

*The split point was knowledge.* Splitting at the touch point  $x = 1/2$  moves each half’s maximizer to an endpoint — and endpoint Bernstein coefficients are function values, so both child enclosures land their ceilings at exactly 0 (the transcript’s `["-1/4", "0"]`, twice) and discharge by one cheap move each. A midpoint-splitting heuristic would have done the same here by luck; on a claim whose touch point is off-center, choosing the split is a contribution only the mover can make. Hold that thought for one section.

*Nobody closed the parent.* The attempted third move on `ob1` was refused, in words that state the discipline; the final status arrived by propagation when the second child discharged, and the parent’s witness is the decomposition itself — `{"dischargedChildren":["ob2", "ob3"]}` — while the exact-tier artefacts live on the leaves.

*The log determines the state.* Five events: one pose and four attempts (the refused call appended nothing). The last attempt’s event carries two closures — the child’s, and the root’s by propagation — and replay applies recorded effects without re-executing any move, which is why the rebuilt workspace is identical even though nothing requires a kernel to be deterministic.

The daemon is this same object held behind a socket. `mtk-session serve` (run from the package checkout as `node src/main.ts serve` at this preview) holds one workspace and speaks newline-delimited JSON-RPC 2.0 over a unix domain socket, or over `stdio` for harnesses that spawn it as a child: one request per line, one response per line, seven methods (`session.info`; `obligation.pose`, `.list`, `.get`, `.moves`, `.apply`; `workspace.log` for the event tail). State lives in the daemon, so clients disconnect and reconnect freely, and errors carry structured codes rather than prose. JSON is a deliberate choice at this one boundary — the clients are foreign by construction: any agent runtime, any language, or a person with `nc` — and no certificate content crosses it: certificates land through the same canon encoding as everywhere else in this book, and the protocol carries menus, selections, and witness summaries.

## 8.11 The strategy layer

In the last listing, the workspace kept the books, the kernels computed the truth, and everything interesting in between — range first because it is cheap, split *there* because that is where  $p$  touches zero — was you. That seat has a name in the session surface: the *proposer*. A proposer is shown the open obligations, the evidence accumulated so far, and the move menus, and asked for one selection at a time. The Executive Summary promised this seat when it described agents driving tactic selection over an obligation workspace “with the strategy intelligence supplied by the reader as the language model of their choice” (chapter 1), and this section is that layer — shaped so that anything can sit in it. The opening page addressed this tutorial to a capable agent doing verification work; over the `serve` socket, that reader holds the seat personally.

The trust statement, precisely. A proposer chooses *which* exact computation runs next — nothing else. It cannot fabricate an outcome: a proposal outside the posted menu is rejected against the menu and the error is fed back; two consecutive failures end the loop with the workspace untouched. It cannot inject a witness: witnesses are constructed by move execution only, behind the no-bare-verdict guard of the previous section. And it cannot upgrade a shortfall into a discharge, because the comparisons happen in exact rational arithmetic inside the claim kinds. Stance 1 gains its corollary: because verdicts never come from the strategist, the strategist may be arbitrarily wrong — confused, overconfident, adversarial — at a cost denominated in budget, never in soundness. The same reason the producer was allowed to be fast and heuristic, applied one level up.<sup>1</sup>

The package ships two proposers, and the contrast between them is the demonstration. The *scripted* proposer is a deterministic cheapest-first ladder per claim kind: no key, no network, the CI path, and the

<sup>1</sup> This seat has a literature: Laurent and Platzer learn to refine proof-search strategies [152], and their oracular programming gives LLM-enabled software a modular foundation in which untrusted oracles answer through checked interfaces [153]; closest to this chapter’s workflow, Kabra and colleagues use language models to automate interactive theorem proving and control synthesis for hybrid games [128].

budget floor any cleverer strategy ought to beat. Here it drives the Quick Start’s claim (section 7.1 — the same claim; there you ran one producer end to end, here a workspace orchestrates a ladder of instruments):

```
$ node src/main.ts demo

  "path":"out/frozenlake-4x4/exact_T10.cbor"}}
strategy ended: solved; moves used: 3
```

(Long lines are wrapped at JSON commas to fit the page; the package’s committed receipts carry both of this section’s transcripts unbroken.) The three attempts are one story told forward. The float sweep is the cross-instrument of section 8.9 in move form: its margin estimate,  $-2 \times 10^{-17}$ , is float for “the claim sits dead even with the optimum” — which the Quick Start disclosed in advance: 815/19683 is the exact ten-step optimum, so this claim has zero slack. The dyadic attempt is a sound certifying lane, and its evidence is exact: a lower bound of  $694681/2^{24}$ , short of the claim by exactly  $24917/(2^{24} \cdot 3^9)$ . The shortfall is structural, not a tuning failure: every reach probability in this model has a power of three for its denominator, the claim is such a number in lowest terms, and no dyadic rational equals it — so a rounded-down dyadic bound sits strictly below a zero-slack claim at every precision, and no kBits fixes it. The workspace records that gap as an exact rational, the evidence routes the escalation, and the exact tier discharges with zero slack, its witness carrying the certificate content — the same content, digest for digest, that the Quick Start produced.

One seam note at this preview: the demo’s remaining transcript lines, not shown above, hand the emitted certificate and a deliberately broken copy of it to an independent checker, which accepts the former and refuses the latter naming the violated obligation. We leave those lines out because that checking surface is mid-migration to consuming certificates the way the Executive Summary describes them — signed, content-addressed commit content, checked by any of the three routes — rather than as files handed to a dedicated binary. The workspace is indifferent to the migration: what it stores is a witness, and what a witness cites is content.

To seat a model instead of the script, supply an OpenRouter key in the environment (OPENROUTER\_API\_KEY; any chat-completions model works, and the router’s default is used if you name none). The model is shown the same view a client at the socket gets, and must answer with one JSON object selecting a move:

```
$ node src/main.ts demo --llm --model google/gemini-3.5-flash
mtk-session demo — the FrozenLake deadline claim, end to end

claim obl: FrozenLake-4x4 (slippery, success 1/3): recorded policy reaches the goal
  within 10 steps with probability >= 815/19683
strategy: llm:google/gemini-3.5-flash
... asking google/gemini-3.5-flash
[1] obl float_sweep -> inconclusive (1 ms) {"estimate":0.04140628969161203,
  "claim":0.04140628969161205,"marginEstimate":-2.0816681711721685e-17}
... asking google/gemini-3.5-flash
[2] obl exact -> discharged (1 ms) {"tier":"exact","bound":"815/19683","claim":"815/19683",
  "certificate":{"bytes":2511,
  "sha256":"66040e596ece30efcbl500350396477f6e4f56d9af1b8f2896c30bece2fc391",
  "path":"out/frozenlake-4x4/exact_T10.cbor"}}
result obl: discharged (via exact)
witness: {"tier":"exact","bound":"815/19683","claim":"815/19683","certificate":{"bytes":2511,
  "sha256":"66040e596ece30efcbl500350396477f6e4f56d9af1b8f2896c30bece2fc391",
  "path":"out/frozenlake-4x4/exact_T10.cbor"}}
strategy ended: solved; moves used: 2
```

The transcript's shape makes the argument. Shown the sweep's dead-even margin, the model — Gemini 3.5 Flash through OpenRouter, in the committed run — selected the exact tier at once: two moves where the ladder spent three, because it read evidence a fixed ladder cannot. Nothing depended on it being right. A worse selection would have cost one extra attempt; nonsense selections would have ended the loop after two rejections with the workspace untouched; and no selection of any kind could have moved a verdict, because routing is the one contribution a strategist can make here and the only one it is allowed. Same claim, same certificate content, same digest: strategy changes the path, never the bytes.

Past the demo, the seat generalizes. `node src/main.ts solve claim.json --strategy llm` poses any statement of a registered kind and drives it the same way (`--strategy scripted` is the no-key floor), and an agent harness that prefers to hold the seat itself connects to serve and speaks the protocol directly. The workspace neither knows nor cares what kind of mind proposes.

## 8.12 Where this goes

You can now construct every kind of object this book's spine runs on — exact scalars, certified enclosures, claim records, derivation rows, certificate documents with their mutant batteries — and you have worked their production from an obligation workspace under two different strategists. Three directions from here, in increasing order of ambition:

- *A worked model at full scale.* The fabrication-line chapter (chapter 17) runs this stack over a model with re-entrant flow, batching, failures, and shared personnel — and shows the checker's economics on the way. The System Catalogue of model types (chapter 12) and the composition patterns (chapter 13) are its reference spine.
- *The operating philosophy.* The Cookbook (chapter 19) is the patterns manual this tutorial has been quietly citing throughout; read it the way you would read *How to Solve It* [200] — before you need it.
- *Sessions under your own harness.* The workspace and the strategy seat (sections 8.10 and 8.11) are importable pieces — workspace, the proposer interface, the RPC client — and two growth directions are yours from here: hold the seat yourself, over the socket, from whatever harness you already run; or register a new claim species by implementing one `StatementKind` (`validate`, `describe`, `moves`, `exec`) whose moves call the builders this chapter taught — which is how the menu discipline extends to specs, judgments, and derivation rows.

A graduation exercise, meanwhile, that needs nothing not already on your disk: FrozenLake has a hitting companion, `dp.cliffwalkingHitting()`. Produce its deadline certificate, read its document, and design its claim-inflation mutant — the matched pair the battery discipline requires — then check the committed corpus to see how close your battery came to the shipped one (expected verdicts are recorded in the receipts beside the artefacts, and the family's sealed row form ships a mutant battery of its own, each entry's expected verdict and violated obligation named in its manifest).

# The Semantic Universe

DRAFT

In our Quantitative Temporal Specification Logic (QTSL), open Systems and their Specs denote in one universe, at consecutive storeys of one tower (Figure 9.1). A System denotes a *belief*: a lower semicontinuous functional on probability distributions over records, whose value at a conceivable joint distribution is the level of *inconsistency* between that distribution and what the System asserts — a reading adopted from Richardson and Halpern [209], and the notion of belief this book commits to throughout [54]. Via the *radial compile*, each belief denotes a closed radial *body* in the space of subprobability distributions over records. The *hyperspace* of closed *sets* of closed bodies is the next storey; Systems are singleton elements of the hyperspace. A Spec denotes a *constructible class* within the hyperspace, i.e., an element of the same hyperspace’s finitary constructible algebra, which constitutes the fibre of Specs. At the hyperspace storey and above, the order of the universe is *inclusion* — membership of a singleton in a class, containment of one class in another — and ultimately,  $\llbracket \text{System} \models \text{Spec} \rrbracket := (\llbracket \text{System} \rrbracket \subseteq \llbracket \text{Spec} \rrbracket)$  (like Willems’ “behavioral approach” [240], but at full imprecise-probabilistic altitude). The pointwise order on beliefs is the same order seen one storey below, exchanged with inclusion by the compile (section 9.6), although specifications which arise through this compile alone can only express safety, not liveness (the incorporation of liveness specs crucially relies on the “hit-and-miss” aspect of hyperspace topology).

Wiring is composition in a double category whose base holds interfaces and wiring patterns and whose fibres hold Specs — the **double category of System Specs**, assembled by a **double Grothendieck**

Figure 9.1: The storeys of the semantic universe, in dependency order, with the section that builds each; the sections follow the same order. On the universe’s radial stock the compile exchanges the pointwise order on beliefs with inclusion of bodies; from the hyperspace storey up, the order of the universe is inclusion. The site dimension runs through every storey above the site: each object is carried window by window and glued along the site’s coverage (section 9.4 and section 9.8).

**construction** whose obligations are formally-verified end to end (section 9.9) and checked with Lean as well as SafeVerify and nanoda. The chapter is written against a single mechanized development, and each storey’s definitions cite their machine counterparts by module and theorem name beside the statement.

**How to read this chapter.** Figure 9.1 is the map. The *causal order* fixes the events and the two relations — causality and chronology — from which the temporal geometry is made (section 9.1). The *site* is derived from that order — its windows are causal diamonds and its coverage is a theorem, not a choice — and, equipped with duration and tangency, governs how records glue into trajectory spaces (section 9.2). A *record* is an observation history over a window’s stages, a classical duration-carrying history along each of its worldlines, and every temporal clause of the specification logic evaluates along a single such timeline (section 9.3); the record carrier over each window of the site is a compact Fell hyperspace, with gluing along the interior coverage — directed covers, at fixed state fibre — a homeomorphism onto a projective limit (kernel-checked, section 9.4). The *universe of beliefs* holds the denotations of Systems: lower semicontinuous level-of-inconsistency functionals on probability distributions over records, ordered pointwise (section 9.5). The *hyperspace* holds their bodies, with Systems as singleton elements and inclusion as the order (section 9.6). The *fibre of Specs* holds the constructible classes, on which conjunction is intersection and disjunction is union, the latter forced (section 9.7). The *composition construction* carries the semantics of wiring: decoration functors on the interfaces-and-wirings base — the authoritative total carrying coupled-DNF presentations of constructible classes as fibre data — each total a pseudo double category with a strict projection that is a discrete double opfibration, all of it kernel-checked (section 9.9). The storeys then assemble: the *Semantic Universe* itself, the chapter’s headline object, is stated whole as the iterated total — Specs over interfaces over site-profiles — in section 9.10. And a final section before the receipts (section 9.12) is the adapter: how the wall fragment — the fragment the shipped checkers actually certify — embeds into the universe, stated only after the universe is complete on its own terms. Four families of material can be deferred without losing the thread. The generalization columns of section 9.2 — causal diamonds, general relativity, open quantum systems, branching time — exist to show that the site is a genuine parameter; unless those instantiations are your interest, what later sections consume from them is only the site contract (F1–F6) at that section’s close. The record carrier (section 9.4) may be skimmed until its final subsection, which lists the four interfaces everything downstream consumes. The mechanization remarks are receipts, not exposition: each names the machine-checked counterpart of the statements beside it, and a reader who trusts the ledger can pass over them. And the three sections after the assembled universe serve readers arriving with specific questions — adequacy (section 9.11) for the modelling catalogue’s squares, the wall fragment (section 9.12) for how possibilistic verdicts embed, and the receipts (section 9.13) for the evidence classes.

## 9.1 The Causal Order

The base storey of the universe is the causal order, from which the site is made. The axioms our construction requires are exactly the order-theoretic fragment of bicontinuity isolated by Martin and Panangaden [171]. In classical  $\mathbb{R}$ -valued time,  $\ll$  is exactly  $<$ ; in relativistic Minkowski spacetime,  $\ll$  denotes reachability by a time-like worldline (strictly less than lightspeed) with nonzero spacetime distance, while  $\leq$  denotes reachability by any worldline (including lightspeed or zero spacetime distance). In discrete time, both  $\ll$  and  $\leq$  are interpreted by  $\leq$ .

**Definition 9.1** (Causal order). (`QtslAux.DiamondSite: ChronologyKit`) A causal order consists of

1. A set  $E$  of *events*;
2. a partial order  $\leq$  of *causality*; and
3. a relation  $\ll$  of *chronology*, such that
4.  $p \ll q \Rightarrow p \leq q$  (chronology is stricter than causality),
5.  $p \leq q \ll r \Rightarrow p \ll r$  and dually
6.  $p \ll q \leq r \Rightarrow p \ll r$ ,
7.  $p \ll q \Rightarrow \exists s. p \ll s \wedge s \ll q$ ,

8.  $\forall p, r, s. p \ll r \wedge p \ll s \Rightarrow \exists q. p \ll q \wedge q \leq r \wedge q \leq s$ , and

9.  $\forall p, r, s. r \ll p \wedge s \ll p \Rightarrow \exists q. q \ll p \wedge r \leq q \wedge s \leq q$ .

The *cone order* of special relativity — events  $(t, x)$  in time  $\times$  space, with  $p \leq q$  when  $\|q_x - p_x\| \leq q_t - p_t$  and chronology the strict cone — satisfies every axiom over a real normed space of any dimension (kernel-checked: `QtslAux.DiamondTopology`, `minkowskiKit`); there the order is genuinely partial — distinct simultaneous events are causally incomparable, so no foliation linearizes it. On a globally hyperbolic spacetime, the causal and chronological relations  $J^+$  and  $I^+$  of the metric satisfy the axioms with room to spare: this is Martin and Panangaden’s theorem [171], which delivers bicontinuity and more — their interval topology *is* the manifold topology, so at that rung the order knows the topology of spacetime outright. And at the opposite pole a *discrete* order — integer ticks — admits no *strict* chronology at all (interpolation fails between consecutive ticks; kernel-checked), a degeneration the next section turns into a feature rather than an exclusion.

Two boundary facts orient everything downstream. First, the *ladder*: how much of a spacetime its causal order determines is graded by the classical causality hierarchy, and this book stands on two rungs of it — strong causality, exactly the condition under which the order’s interval topology (generated by the chronological diamonds  $I^+(p) \cap I^-(q)$ ) is the manifold topology, a theorem Martin and Panangaden quote from Penrose [171]; and global hyperbolicity, the rung at which reconstruction from the order is complete. Second, the *limit* of the method: by the theorems of Hawking–King–McCarthy and Malament [113, 170], the causal order of a distinguishing spacetime determines its topology, its differential structure, and its *conformal* class — and nothing more. Durations are precisely the conformal factor the order forgets. Everything the order does know is *derived* in the next section (Definition 9.2) — windows, coverage, and the coverage’s well-behavedness are theorems of  $(\leq, \ll)$ , not choices — and everything it cannot know, **duration** and **tangency**, enters there as additional declared structure. The division of data is a theorem in both directions, and the structured-site definition of the next section is organized around it.

## 9.2 Spacetime as a Structured Site

The site is *derived* from the causal order — windows and coverage are theorems of  $(\leq, \ll)$  — while **duration** and **tangency** are declared on top. This section gives the derived object first (Definition 9.2), then the classical instantiation — the value at which every classical artefact of this book lives — and the factored form of the construction, so that what is derived and what is declared stay visibly separate.

### 9.2.1 The Derived Site

**Definition 9.2** (Spacetime site). (`QtslAux.DiamondTopology`) Let  $(E, \leq, \ll)$  be a causal order (Definition 9.1). The *spacetime site* of  $(E, \leq, \ll)$  is the site whose

1. *objects* are the causal diamonds  $[a, b] = \{c \in E : a \leq c \leq b\}$  with  $a \leq b$ , ordered by containment — morphisms are inclusions of subdiamonds; and whose
2. *coverage* is the *derived interior topology*: a sieve on  $[a, b]$  covers precisely when it contains the inclusion of every chronologically interior subdiamond — every  $[c, d] \subseteq [a, b]$  with  $a \ll c$  and  $d \ll b$ .

No further data enter: the spacetime site is a function of the causal order.

That the coverage is a Grothendieck topology is a theorem of the causal-order axioms, kernel-checked in closed form (`diamondTopology`): pullback stability is the two absorption laws (axioms 5–6), and local character is density (axiom 7) applied at both endpoints. The consumption is exact — the topology uses only axioms 4–7 of Definition 9.1, never the filteredness axioms 8–9, which feed the descent arguments of section 9.4 instead. The order-theoretic demands factor as: *interpolative mixing buys the coverage; filteredness buys descent*. (The mechanized statement quantifies over the full kit while its proof consumes only the coverage half; the factoring is recorded in the module.)

On a diamond that is not chronologically thick ( $a \not\ll b$ ) the covering condition is vacuous, so every sieve covers — in particular the empty one, which forces every sheaf to a point on that diamond: the derived form of the classical excision of duration zero (`mem_of_not_thick`). More generally the chronology acts as a *descent dial*. The degenerate choice  $\ll = \leq$  is admissible and its derived topology is the *coarsest*

*Grothendieck topology* — only the maximal sieve covers, so sheaves are exactly presheaves and no gluing is ever demanded (`mem_diamondTopology_degenerate_iff`); the discrete order refuses the strict chronology outright (interpolation fails between consecutive ticks; kernel-checked, `int_lt_no_chronologyKit`), so integer ticks sit at the dial’s coarsest end; dense orders admit the strict chronology, whose covers are the genuinely interior ones and whose sheaf condition is the gluing this chapter uses.

Four instances calibrate the definition. The value at  $(\mathbb{R}, \leq, <)$  is the classical interval-domain site, identified cover-for-cover with the site of Schultz and Spivak through the homogeneity quotient below (Remark 9.5). The value at the cone order is the Minkowski site, kernel-checked over a normed space of any dimension (`minkowskiKit`). The value on a globally hyperbolic spacetime exists by Martin and Panangaden’s theorems [171] — cited rather than mechanized, since the site consumes only the order axioms and Lorentzian geometry never enters the development. And integer ticks ride the degenerate dial setting, the strict one being refused by their order.

A spacetime site arrives with its stage data for free — a diamond’s stages are its own events under the induced order, restricted along inclusions — so it supplies outright the site and stage clauses (T1)–(T2) of the structured definition this section builds toward. What it cannot supply is exactly what section 9.1’s closing division of data says it cannot: duration and tangency, which Definition 9.4 declares on top.

## 9.2.2 The Classical Instantiation

The site every classical artefact of this book lives on is the value of Definition 9.2 at the causal order  $(\mathbb{R}, \leq, <)$ , taken through one further, deliberate step — a homogeneity quotient. Schultz and Spivak [217] take as base the interval domain  $\mathbb{IR}$ : closed intervals  $[d, u]$  ordered by reverse inclusion, with  $[d', u'] \ll [d, u]$  precisely when  $d' < d$  and  $u < u'$ . The coverage is generated by the way-below relation alone — an interval is covered by the family of its strictly interior subintervals — and behaviour types are sheaves for that coverage: a behaviour over a window is exactly a compatible family of behaviours over its interior subwindows. Two design decisions of theirs matter for what follows. First, the finer coverage that would let two behaviours meeting at a single endpoint glue is deliberately omitted; gluing across abutting windows is a property a behaviour type may have, not one the site imposes. Second, they quotient by translation: the quotiented site’s objects are *durations*  $\ell \geq 0$ , and absolute time survives the quotient as an internal object Time — the behaviour type of a clock. The quotient does not delete absolute time; it *demotes* it, from base structure to component. That demotion is the categorical form of a commitment the model-type inventory (chapter 12) states operationally: clocks are internalized as mechanism state, and no artefact of the toolkit carries a global timeline field.

**The construction, factored.** Read as a recipe, the classical construction splits into two stages with very different appetites, and the split is what makes “time as a site parameter” more than a slogan:

| stage                | required structure                                                                                                                                     | output                                                        |
|----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------|
| order-theoretic core | a continuous predomain                                                                                                                                 | the way-below coverage and its sheaf topos                    |
| homogeneity quotient | a coverage-compatible free action whose projection is a discrete bifibration with flat descended covers — or, directly, a continuous quotient category | duration objects; absolute time demoted to the internal clock |

The unquotiented stage is purely order-theoretic: the way-below coverage is definable on an arbitrary continuous predomain, and the sheaf topos exists with no real arithmetic, no field structure, no metric anywhere in the site data. The homogeneity quotient is the demanding stage; here is its requirement, stated formally.

**Definition 9.3** (Homogeneity quotient). Let  $(\mathcal{T}, J)$  be a site and let a group  $G$  act on  $\mathcal{T}$  by coverage-preserving automorphisms (the image of a  $J$ -covering family under each  $g \in G$  is  $J$ -covering), freely on objects. Suppose:

- (Q1) the orbit projection  $\pi: \mathcal{T} \rightarrow \mathcal{T}/G$  onto the quotient category is a *discrete bifibration* — every morphism of  $\mathcal{T}/G$  has exactly one lift along  $\pi$  through any chosen lift of its source, and exactly one through any chosen lift of its target; and

(Q2) the *descended families* — images  $\pi(F)$  of  $J$ -covering families  $F$  — generate a coverage  $J/G$  on  $\mathcal{T}/G$  (*flat descent*: a pullback of a descended cover along any morphism of  $\mathcal{T}/G$  is refined by a descended cover).

The *homogeneity quotient* of  $(\mathcal{T}, J)$  by  $G$  is the site  $(\mathcal{T}/G, J/G)$ .

The input of the construction is the *action*, not a duration — at this generality no metric structure appears anywhere in the hypotheses. Duration names the *output* in the favourable case: when  $\mathcal{T}$  is a spacetime site whose duration structure (T3) is  $G$ -invariant and is a *complete* orbit invariant, the quotient's objects are canonically the durations, which is exactly the classical situation —  $G = (\mathbb{R}, +)$  translating the interval domain, the orbit of  $[d, u]$  determined by  $\ell = u - d$ , morphism orbits the shave-off pairs  $[r \mid s]$ , and (Q2) discharged through lattice structure on the translation parameters (coproducts of wavy arrows taken by componentwise maxima) — one sufficient realization, not part of the requirement. Neither direction of the association is automatic: a site may carry a perfectly good duration and admit no qualifying action (nothing to quotient by), and a quotient may exist whose objects no scalar names — Minkowski diamonds under spacetime translations alone quotient to displacement *vectors*, and only the further Lorentz quotient collapses the invariant to the scalar proper time. A candidate time base therefore pays for time-homogeneity separately from existence — and the two generalization columns below sit on opposite sides of that bill. (The classical value of the quotient is kernel-checked through the identification of Remark 9.5; the definition at this generality is stated in prose, an obligation of the ledger if a second instantiation ever consumes it.)

Both claims in the first row are now theorems at the generality of Definition 9.2: the way-below coverage is that definition's derived interior topology — on diamonds, way-below *is* componentwise chronology, the theorem the causal-diamond column below records — and its well-behavedness, its consumption of the order axioms, and its descent dial are theorems of the causal-order axioms, stated with that definition. The homogeneity quotient of the second row is the classical column's own step, and everything the table demands of it is demanded of the quotient alone.

### 9.2.3 Duration, Tangency, and the Structured Site

Two additional structures are necessary to feed the two families of proof obligations the certification interface emits.

*Duration* is the metric-temporal axis: it types deadline windows  $F_{\leq T}$  and until windows, the spectral shift  $\theta$  of a decay certificate (units: inverse duration), and the rate and jitter bounds carried by clock morphisms. In the classical site duration is native and visible — the quotient's objects literally are durations.

*Tangency* is the differential axis. The ordinary instance first: for an ODE  $\dot{x} = u(x)$  on a state space  $S$ , the dynamics assigns  $u(x) \in T_x S$ , a certificate sees it through the derivative pairing  $dV_x(u(x))$ , and a tangency abstracts the assignment  $x \mapsto T_x S$ . In general — in the sense of Capucci and Myers [37] (following Libkind and Myers' doctrine of dynamical systems) — it is a base category of state spaces, a fibration of *action bundles* over it, and a section assigning to each state space its bundle of admissible changes. A dynamics is a map *into* the bundle the tangency selects; the infinitesimal generator — the object the certification interface actually touches — is that dynamics presented through its induced action on certificate observables, which in the ODE instance is exactly  $V \mapsto dV(u(\cdot))$  and in other doctrines is the doctrine's own generator form (a jump kernel's integral operator, an open-quantum generator's trace pairing). At this generality, tangencies whose bundles are powersets or distribution spaces are legitimate, which is exactly the slack a jump kernel or an open-quantum generator occupies without any change to the site.

**Definition 9.4** (Structured spacetime site). A *structured spacetime site* is a site equipped with window, duration, tangency, and stage-space structure, as follows.

(T1) *The site*. A small category  $\mathcal{T}$  together with a coverage  $J$  assigning to each object a collection of covering families. Objects of  $\mathcal{T}$  are called *windows*; the coverage governs how behaviours — and in particular records — over the members of a covering family glue to a behaviour over the covered window. The site enters the semantics through this gluing role only; no satisfaction clause of the specification logic consults it.

- (T2) *Underlying stages.* A functor  $|-|: \mathcal{T} \rightarrow \mathbf{Pos}$  assigning to each window  $W$  a partially ordered set  $|W|$  of *stages* and to each morphism  $u: W' \rightarrow W$  an order-embedding  $|u|: |W'| \hookrightarrow |W|$ . A *timeline* in  $W$  is a nonempty chain (totally ordered subset)  $\gamma \subseteq |W|$ . When the site is the spacetime site of a causal order (Definition 9.2), this clause is supplied outright:  $[[a, b]]$  is the diamond's own event set  $\{c: a \leq c \leq b\}$  under the restriction of  $\leq$ , and  $|u|$  for a subdiamond inclusion is the inclusion of event sets. In the classical instantiation  $(\mathbb{R}, \leq, <)$  every  $|W|$  is then totally ordered and is its own maximal timeline; in relativistic instantiations  $|W|$  is genuinely partial and its timelines are the (segments of) worldlines it contains.
- (T3) *Duration structure.* For each window  $W$  and each timeline  $\gamma$  in  $W$ , a duration functor  $\delta_\gamma$  on  $(\gamma, \leq)$  satisfying (R1)–(R2) of Definition 9.6 in the next section — reflexivity at zero, and additivity along the order. The per-timeline indexing is load-bearing, not a hedge: a single duration functor on all of  $|W|$  would force  $\delta(s, u) = \delta(s, t) + \delta(t, u)$  through *every* intermediate stage  $t$  — path-independence of elapsed time — and proper time in a relativistic window is path-dependent (the twin paradox; the reverse triangle inequality makes the straight worldline strictly longest). Duration is additive on the nose *along* each worldline and only there, which is why (T3) is declared per timeline, subject to two naturality conditions:
- (D1) (*restriction*) if  $\gamma' \subseteq \gamma$  are timelines in  $W$  with  $\gamma'$  order-convex in  $\gamma$ , then  $\delta_{\gamma'}$  is the restriction of  $\delta_\gamma$  (convexity is load-bearing: the two-stage sub-timeline of a bent worldline must be free to disagree with the bent valuation, else additivity returns through every intermediate stage — the collapse this clause exists to refuse; window restrictions are always convex, stage sets being diamonds);
- (D2) (*transport*) for every morphism  $u: W' \rightarrow W$  and timeline  $\gamma$  in  $W'$ , the embedding  $|u|$  carries  $\delta_\gamma$  to  $\delta_{|u|(\gamma)}$ : durations of pairs of stages are preserved.
- (T4) *Tangency structure* (in the sense of Capucci and Myers, following Libkind and Myers' doctrine of dynamical systems). A *tangency* is a triple  $(\mathcal{B}, \pi: \mathcal{E} \rightarrow \mathcal{B}, T)$  consisting of a category  $\mathcal{B}$  of state (and observation) spaces, a cloven Grothendieck fibration  $\pi: \mathcal{E} \rightarrow \mathcal{B}$  of *action bundles*, and a section  $T: \mathcal{B} \rightarrow \mathcal{E}$  of  $\pi$ , assigning to each state space  $S$  its bundle  $(T_s S)_{s \in S}$  of *admissible changes*. (The Roman  $T$  is reserved for the tangency section; the italic  $T$  of Definition 9.6 is a record's stage set.) A *dynamics over the tangency* is a map *into* the bundle the tangency selects: on state space  $S$  with input/parameter space  $A$ , an assignment  $u: (s, a) \mapsto u(s, a) \in T_s S$ . When the tangency is the ordinary tangent-bundle tangency of a smooth state space, the induced action on a certificate observable  $V$  is the pairing  $V \mapsto dV(u(\cdot))$ ; for the other legitimate tangencies — powerset bundles (nondeterministic step relations), jump-kernel and distribution-space bundles, operator-valued generators — the induced action is presented doctrine-specifically, and no single formula of that shape is asserted at full generality.
- (T5) *Stage spaces* (Fell-readiness). For each window  $W$  a topology on the stage set  $|W|$ , compatible with the duration structure in the following sense: writing  $d_\gamma(s, t) := \delta_\gamma(s \wedge t, s \vee t)$  for the symmetrization of a timeline's valuation — an extended pseudometric on  $\gamma$ , by (R1)–(R2) — each  $d_\gamma$  is continuous on  $\gamma \times \gamma$ , and on every timeline where  $d_\gamma$  separates stages the subspace topology is the  $d_\gamma$ -metric topology. Under that topology the *stage space*  $S(W)$  is required locally compact, second-countable Hausdorff, with each morphism's embedding  $|u|$  a proper topological embedding. (Zero-duration pairs of distinct stages — hybrid jumps — are permitted; there  $d_\gamma$  separates nothing, and the stage space does not owe them separation: same-instant stages share a stage-space point, and the carrier presents them as one multivalued instant of the record's graph — the closed-graph doctrine of section 9.4, under which any jump is multivalued at the moment it happens.)<sup>1</sup>

Axioms (D1)–(D2) say exactly that living-on-a-timeline is a notion stable under restriction of windows and under the site's morphisms, which is what the gluing role (T1) requires; the records themselves — along a timeline and over a general window — are section 9.3's subject.

Clause (T5) feeds the record carrier of section 9.4, an adopted construction with kernel-checked strata. (T3) is the topology supply on timelines: the site's metric axis fixes the stage topology along every separating

<sup>1</sup>For globally hyperbolic instantiations (T5) is a *precision* in exactly the way Remark 9.5 exhibits classically: there the stage-space topology is itself order-derived — on such a spacetime the interval topology generated by the chronological diamonds is the manifold topology (Martin and Panagaden [171]) — so the clause records a topology the order already knows rather than supplying a new one.

timeline outright and constrains it (by continuity) along the rest, and (T5) asks only for a compatible ambient extension — in the classical instantiation the valuation metric *is* the stage topology — the hybrid column shares that stage space verbatim — so the clause is a precision there, not a new structure. Tangency’s role at the carrier tier is equally specific: it types the one metric hypothesis the record class keeps — a speed bound, a trajectory whose difference quotients lie in a fixed ball of the tangency’s action bundle, measured against duration — so the two site axes jointly type the record layer’s single metric hypothesis, exactly as they jointly meet in the decay row  $\mathcal{AV} \leq -\theta V$ , which pairs a tangency-typed operator on the left with an inverse-duration scalar on the right. Obligation families sort cleanly: infinitesimal-generator rows (*generator rows*, hereafter) and interior rows are tangency; window arithmetic and spectral shifts are duration; reset rows are neither (jumps consume zero duration); nonnegativity rows are pointwise and touch neither axis. The tangency clause is stated at this generality in prose; the mechanized development is parametric over it — every kernel-checked artefact consumes tangency only through the generator-row typing of its concrete instances — and the abstract object is an obligation of the ledger.

*Remark 9.5* (The classical instantiation, quantitatively). The temporal type theory of Schultz and Spivak is the value of the site parameter at which every classical artefact of this book lives — and the identification is functorial, kernel-checked at the site and behaviour tiers: the spec tier’s classical windows map onto the quotient site by the translation quotient, with unique lifts in both directions and covers corresponding exactly to covers (a wavy arrow is a strictly interior inclusion), the motivating behaviour type of trajectories is the site tier’s own trajectory presheaf up to natural isomorphism (`SuFunctor.Site.TemporalTypeTheory: anchorQuot, anchorTrajIso`), and behaviour subtypes include into the double category of System Specs — satisfaction is behaviour membership, wire transport is behaviour pullback, strictly (`SuFunctor.Site.BehaviorSpec: ttObject, satAt_specOfBehavior_iff, wSpecMap_specOfBehavior`).

1. *Site*. The base poset is the interval domain  $\mathbb{IR} = \{[d, u] : d \leq u\}$ , ordered by reverse inclusion, with way-below relation  $[d', u'] \ll [d, u]$  precisely when  $d' < d$  and  $u < u'$ . The coverage is generated by the way-below relation alone: an interval  $[d, u]$  is covered by the single family of its strictly interior subintervals  $\{[d', u'] : d < d' \leq u' < u\}$ . The finer coverage that would let two behaviours meeting at a shared endpoint glue is deliberately omitted: endpoint gluing is a property a behaviour type may have, not one the site imposes. This base is itself the derived object: the interval domain is the diamond poset of the causal order  $(\mathbb{R}, \leq, <)$ , and its interior coverage corresponds cover-for-cover — through the anchored-window identification below — with the derived topology of that order, kernel-checked (`SuFunctor.Site.CausalConcordance: mem_interiorTopology_iff_derived, wavy_mem_iff_derived`). Read at the spacetime level, the identification is also a diagnosis: a time-window with all of space carried in the state fibre is the causal diamond of a world with instantaneous propagation, so as a site the classical column encodes absolute simultaneity — the  $c \rightarrow \infty$  degeneration, in which diamonds flatten to time-slabs — and space is carried by the wiring and the fibres, never by the site.
2. *Homogeneity quotient* (Definition 9.3). Quotienting by translation yields the site whose objects are durations  $\ell \geq 0$  and whose morphisms are shave-off pairs  $[r \mid s]$  with  $\ell = r + \ell' + s$ ; the covering families are those with strictly positive margins  $r, s > 0$ . Absolute time survives the quotient as the internal clock object `Time`, demoted from base structure to component.
3. *Duration structure*. Native and visible: the quotient site’s objects literally are durations, morphism data are duration differences, and the induced valuation on any timeline  $\gamma \subseteq \mathbb{R}$  is  $\delta_\gamma(s, t) = t - s$ .
4. *Tangency structure*. Ordinary calculus: state spaces are smooth (in practice carved by polynomial data; the exact class is fixed below) spaces, the tangency is the tangent-bundle section, a dynamics is a vector field presented as drift data, and the induced action on a certificate observable  $V$  is the Lie derivative row that drift obligations bound.
5. *Stage spaces*. (T5) holds on sight:  $S(\ell)$  is the compact interval  $[0, \ell]$  with the metric  $d_\gamma(s, t) = \delta_\gamma(s \wedge t, s \vee t)$  its own duration functor induces by symmetrization, and the interior covers’ pair-filteredness is kernel-checked in this repository at bicontinuous-poset generality (module `QtslAux.DiamondSite`; the causal-diamond column below is the same theorem’s other instance). The hybrid column shares this stage space verbatim: jumps and resets are carrier facts (multivalued instants), not stage-space structure, so hybrid windows are the classical windows.

For contrast on the duration axis: in the causal-diamond instantiation the site *qua* poset carries only the causal order, and duration data — proper time along timelines — is strictly additional structure, supplied densely rather than per-clock. That divergence in presentation (object-valued durations in the classical quotient; densely supplied proper time on worldlines in the relativistic column) is why (T3) axiomatizes duration by its *induced valuations on timelines*, the invariant form both presentations share and the only form the satisfaction clauses of Remark 9.7 consume.

### 9.2.4 The State Sheaf, and Where the Carving Class Lives

The window-by-window state spaces of a System assemble into a *state sheaf*

$$\mathcal{V}: \mathcal{T}^{\text{op}} \longrightarrow \mathcal{B},$$

a presheaf valued in the tangency’s own base category, so that (T4)’s action-bundle fibration composes with  $\mathcal{V}$  to give each window its bundle of admissible changes. A constant  $\mathcal{V}$  recovers the fixed state spaces every classical artefact uses; a genuinely varying  $\mathcal{V}$  — mode-dependent state spaces, stagewise phase-space reductions, time-varying constraint manifolds — is the structural home of time-inhomogeneity, and under it the time-inhomogeneity lemma splits: its state face is absorbed into the sheaf itself, and its law face reprices to a classical projective limit of compact metrizable systems along a countable tower of windows (section 9.4).

Three commitments govern the fibres of  $\mathcal{V}$ , each with its reason, and with the division of labour stated first: the demand on fibres is intrinsic and topological; the carving class of the next paragraph is how a fibre *certifies* it; and compactification is an *operation* applied to fibres, never a condition on them. The commitments: *locally compact fibres* (Hausdorff, second countable — what the carrier’s Hausdorff theorem consumes, and with second countability it is exactly Polish local compactness, so the same demand buys the denotation stack its standing structure;  $\sigma$ -compactness follows and is what makes the compactified fibres metrizable); *fibrewise cemetery* ( $\mathcal{V}^+(W) := \mathcal{V}(W) \cup \{\infty_W\}$ , the one-point compactification, an operation at the carrier tier — escape-to-infinity becomes an ordinary observation value, and mass leak, killing, and divergence keep their standard readings, per window; the operation lands outside the carving class and owes it nothing); and *proper restriction maps* (what makes the carrier’s pushforward legs Fell-continuous; automatic for the constant sheaf and for mode-restriction embeddings). For a sector carved in  $\mathbb{R}^n$ , local compactness is equivalent to being locally closed — open  $\cap$  closed — which is checkable from carving data; that equivalence is why the certificate below asks local closedness per sector, and a disjoint union of such sectors is locally compact outright, every summand clopen.

The carving class of the fibres is fixed as follows: fibres are locally closed  $\omega$ -semialgebraic sets — countable unions of pieces, each carved in some  $\mathbb{R}^n$  by finitely many polynomial inequalities with *rational* coefficients and finite degree, degrees unbounded across the family — with proper continuous countably-piecewise-polynomial maps, the local polynomial representatives again with rational coefficients. (The coefficient pinning is definitional, not a presentation nicety: over unrestricted real coefficients,  $\{x \geq \pi\}$  is a piece, and the exact-data property below silently dies.)<sup>2</sup> The class decomposes the  $\omega$ PAP spaces of Huot, Lew, Mansinghka, and Staton [117] along their two independent axes — countable piecing, and analytic rather than polynomial carving functions — and adopts exactly the first. The reasons, briefly, because each matters. *Demand*: countable piecing is what discrete-mode models actually need — counters, queues, birth-death populations, program-mode structure are  $\mathbb{N}$ -shaped, definable in no o-minimal structure, and  $\omega$ -semialgebraic in degree-one pieces on sight. *Exactness*: the intermediate class is the largest for which every piece remains finite rational data, so the certificate stratum of Remark 9.42 keeps exact-rational rows piece by piece, with countable piecing expressed by the language and discharged shape-uniformly at the certificate stratum (Remark 9.42: plates, pooled aggregate coordinates, count-budget rows as optional tightenings) rather than paid for by the semantics; full  $\omega$ PAP would surrender domain-exactness (piece

<sup>2</sup>Underneath the site’s commitments sits the mechanized ambient category — module family `SuFunctor.StateSpace` of the proof-artefact repository: objects  $\omega$ -semialgebraic subsets of real ambients, morphisms countably-piecewise-polynomial maps, with finite limits and common-ambient countable coproducts held concretely, and local closedness the membership bridge to the local compactness the carrier consumes. Properness and continuity are the site’s two extra demands on restriction maps, made for the carrier’s sake, never fields of the ambient category’s morphisms. The state-space category proper is this category’s *free countable coproduct completion*: a state space is a countable family of  $\omega$ -semialgebraic sectors, each carved in its own finite-dimensional rational ambient, with all countable coproducts — disjoint, universal, no common ambient asked — finite limits componentwise, and the exact-data story intact through one dimension-tagged countable carving alphabet (`SuFunctor.StateSpace.FamCat`, `FamCoproducts`, `FamLimits`, `FamCompletion`).

membership and guard side-conditions leave the exact fragment), while its value-side content — analytic densities, regular guards — lives at the law tier, where the calculus’s standing hypotheses already name it, untouched by this dial. *Freedom*: the record carrier of [section 9.4](#) is fibre-class-blind — its topological development consumes only the three commitments above, never the carving class — so the dial can be widened later at zero cost to any existing proof; narrowing is what would cost. Membership in the class of fibres is a real condition, not a formality:  $\mathbb{Q} \subseteq \mathbb{R}$  is  $\omega$ -semialgebraic and nowhere locally compact — excluded by the demand, and by its certificate ( $\mathbb{Q}$  is locally closed in no neighbourhood) — and adoption-time checks use a catalogue of sufficient patterns ( $V$  closed;  $V$  a topologically disjoint union of locally closed semialgebraic pieces — the bag pattern of every discrete-mode hybrid;  $V$  compact). The separation of concerns above is what keeps the class this small: the one-point compactification of an infinite bag is not a bag under any re-presentation (compact and infinite, it admits no infinite clopen partition, and finitely many semialgebraic pieces would make it semialgebraic, which  $\mathbb{N}^+$  is not) — so a class required to contain its own compactifications would be forced open to unions whose pieces accumulate. No such demand is made: the cemetery is an operation at the carrier tier, its output compact metrizable directly from the fibre’s local compactness and second countability, and the carving class never needs to carve  $\infty_W$ .

### 9.2.5 First Generalization Column: Causal Diamonds

For a globally hyperbolic spacetime  $(\mathcal{M}, g)$ , Martin and Panangaden [171] proved that the causal intervals  $[a, b] = \{c : a \leq c \leq b\}$  under reverse inclusion form a continuous domain whose way-below relation is componentwise chronology ( $[a, b] \ll [c, d]$  iff  $a \ll c$  and  $d \ll b$ ), and — the theorem that turns an analogy into an instantiation — that the category of globally hyperbolic posets is *equivalent* to the category of interval domains. The causal-diamond site is the verbatim transposition of the classical coverage to this domain: cover a diamond by its chronologically interior subdiamonds; the classical interval domain is the  $(0+1)$ -dimensional case of the same construction. The interior coverage is well-behaved at exactly the generality one would hope — for every bicontinuous poset, the interior covers of a diamond with  $a \ll b$  are nonempty and pair-filtered — and this is kernel-checked in this repository at exactly that generality (module `QtslAux.DiamondSite`): the mechanization consumes only the order-theoretic fragment of bicontinuity, no manifold and no compactness anywhere, and the classical interval domain is literally its dense-linear-order instance. The boundary caveat is likewise settled: nonemptiness of the interior covers is *equivalent* to chronological thickness ( $a \ll b$ ) — an iff, kernel-checked — so degenerate and null-related diamonds are covered by nothing, and the subsite of chronologically thick diamonds is the coverage’s maximal domain, the verbatim generalization of the classical excision of duration zero. (The reopening condition is named in the closing ledger: an application with claims on the null boundary would change the balance in favour of retaining boundary objects; nothing classical waits on it.) The diamond column is also the natural route to partial differential equations: a field over a spacetime region is a behaviour over a window whose stages are events, and hyperbolic problems are diamond-local in exactly the sense the interior coverage expresses — finite propagation speed is why energy estimates live on causal diamonds. PDE dynamics enter the adequacy strand today with space carried by the wiring rather than by the site — spatially extended cells over classical time windows ([section 9.11](#)) — and the diamond column is where space moves from the wiring into the site. The certificate stratum has a matching design: the spatial variable enters as a declared coordinate wire, so a certificate over PDE states is a spatially plated hypernet — one finite object denoting a region-indexed family of rows — and contraction along the spatial extent is a symbolic integral, discharged by differentiating polynomial witnesses rather than by enumerating a mesh; region subdivision then joins site coverage and wiring as a third composition axis, interior to the fibre, and all three are valuation-shaped.

A generic curved spacetime has trivial isometry group, so the homogeneity quotient is simply not exercised — which is semantic correctness, not damage: physics on a curved background is not translation-invariant, and behaviour types there *should* be diamond-indexed. What replaces the internal clock is the worldline: a timelike curve with proper time induces a map of sites from the classical interval site into the diamond site (proper-time intervals to the causal hulls of worldline segments), and that map is the curved-case clock — per-interface data, exactly as the toolkit already carries clocks. The clock-map’s site-level checks are kernel-checked in the same module: for any strictly chronology-preserving map out of a dense linear time order carrying the two endpoint-approximation properties that openness of the chronological past and future supplies, the induced diamond map is monotone for containment, lands in the thick subsite, carries interior-cover members to interior-cover members, and preserves covers in cofinal form. What remains cited rather than proved is the manifold-level instantiation: that a timelike worldline with proper

time satisfies those approximation properties in a distinguishing spacetime. Duration structure is proper time along records; tangency is the manifold's tangent bundle. And the division of data is sharp in a way worth recording: by the Hawking–King–McCarthy/Malament theorems [113, 170] a chronological isomorphism between distinguishing spacetimes — globally hyperbolic ones qualify — is automatically a smooth conformal isometry: the order determines the conformal class and nothing more. Durations are precisely the conformal factor the order forgets, and must be supplied as additional structure — densely, not per-clock. “The site is structured” is not a convenience of presentation; in this column it is a theorem about what the order alone cannot know.

**General relativity, in two grades.** The phrase “causal diamond” invites a stronger reading than the diamond column delivers, so here is exactly what it is — and is not — a semantics for. On any *fixed* globally hyperbolic background, curved or flat, the *bare derived site* exists outright: the causal and chronological relations of the metric satisfy the causal-order axioms by Martin and Panangaden's theorems [171], so Definition 9.2 instantiates there with no new machinery — the site consumes only the order, and Lorentzian geometry itself never has to enter the mechanization — while the column's supplied structures and owed obligations (duration, tangency, the record locus over general supports) are exactly those named elsewhere in this section, neither better nor worse off for the curvature. Background *independence* is different in kind, and no fixed site can even state it: in full general relativity the metric is a field, so the causal order depends on the solution while the fields live over the order. Because the site is derived — a function of the order — that circularity becomes an ordinary, if open, indexing problem rather than an inexpressible one: an outer storey indexed by causal orders (equivalently, within the distinguishing class where Malament's rigidity theorem [170] governs, by conformal geometries), with the fibre over each order the behaviour-and-spec tier over its derived site; in each fibre a solution record carrying exactly the data the order forgets — the conformal factor, entering as (T3) duration structure, together with matter fields; and self-consistency as a section condition, that the order indexing the fibre is the order its own metric-record induces. Einstein's equations then enter as a constraint on that locus — which order-factor-matter triples are admissible — not as site structure. The composition construction of section 9.9 already indexes interfaces by site profiles, so indexing of this shape has a precedent in this book; the outer storey itself — its morphisms beyond isomorphisms, its coverage — is future work, named in the closing ledger so the column's boundary stays visible (the groupoid part is no longer owed: transport along chronology-respecting order-isomorphisms is kernel-checked, module `QtsAux.QuantumCovariance`): fixed backgrounds are covered, and background independence is designed for, not built.

## 9.2.6 Second Generalization Column: Open Quantum Systems

**The modest route.** An open quantum system enters as one more mechanism profile — Hamiltonian plus noise operators, with the standard Gorini–Kossakowski–Sudarshan–Lindblad generator — and its master-equation flow  $t \mapsto \rho_t$  is a deterministic continuous behaviour valued in density operators: an ordinary behaviour type over the *existing* site. Where measurement enters, the measurement record is a classical stochastic process, and the record-level probability operators of section 9.5 already speak about it. Stability obligations transpose with the dictionary regions  $\mapsto$  projections, evaluation  $\mapsto$  trace pairing; the generator row becomes an operator inequality  $\mathcal{L}(V) \preceq -\gamma V + \zeta \mathbb{1}$ , checked by positive-semidefiniteness machinery the kernel already trusts for other purposes — under this column's stated hypotheses, which are design content and not fine print: finite-dimensional mechanisms (or bounded generators) only, with truncations of infinite-dimensional systems entering only under explicitly represented truncation error. That the stated hypotheses suffice is not only asserted: the transport theorem behind this row — Born-pairing positivity, the Loewner-monotone generator-row step, the sharp exponential bound, trace conservation as a theorem of the trace-annihilating generator form — is kernel-checked in this repository at the finite-dimensional stratum (module `QtsAux.OpenQuantum`). No site change occurs anywhere on this route, and the column as a whole is a design with its costs stated, graded in section 9.13, not a shipped instantiation. What the route does *not* deliver is event-level claims about measurement outcomes from stability certificates alone; those await a quantum transport theorem in certificate form, and the gap is named debt, not fine print.

**The same column, the deeper route: quantum states against the site itself.** The modest route leaves the site untouched by design. Its natural sequel asks what happens when quantum states meet

the site's own machinery — the records of [section 9.3](#) and the coverage of [Definition 9.2](#) — and the sequel is kernel-checked at the finite-dimensional stratum, on both sides. On the record side: a family of record observables — Hermitian, mutually orthogonal, correlated with the branch alternatives at the state; hypotheses deliberately weaker than the projections of the consistent-histories literature — forces the decoherence functional of its branch family diagonal, so the branch weights form an honest finitely additive probability row, the object the belief storey consumes. That is Gell-Mann and Hartle's records-imply-consistency direction [86], mechanized together with its biconditional for pure exhaustive families and witnesses that no hypothesis can be dropped (module `QtslAux.QuantumRecords`); the converse implication fails by kernel-checked witness — there is a weakly consistent branch family admitting no record family at all — so records genuinely select among consistent decompositions rather than relabelling them. On the coverage side: over a two-site observable net on Minkowski diamonds, gluing fails inside the state body, and it fails where entanglement lives. The Bell state and the maximally mixed state restrict identically along every member of a spacelike pair-cover yet differ; at pure marginals the same gluing is rigid (a theorem, not an example); and the derived interior coverage *refuses* the failing cover, while every cover it does certify separates (module `QtslAux.QuantumDescent`). The boundary this section drew for order-theoretic reasons — interior covers only — is the boundary quantum mechanics needs. The two sides then meet in a single kernel-checked sentence: the state presheaf over the net is separated at derived covers and provably not separated at the spacelike pair-cover, and one record row distinguishes the two state classes that the entire pair-cover cannot (`recordShadowQ_separates_bell_mixed`, module `QtslAux.QuantumStates`) — records carry information that region-by-region restriction structurally misses, which is this chapter's records thesis in theorem form.

**The locally covariant fragment.** These are not scattered observations; they are the kinematic axioms of algebraic quantum field theory. Observables have been indexed by causal diamonds since Haag and Kastler [103], and the locally covariant refinement of Brunetti, Fredenhagen, and Verch [29] takes as morphisms the isometric embeddings whose images are causally convex — causal convexity being this section's diamond condition — so the index category of rigorous quantum field theory is a derived site, and has been since 1964. One kernel-checked structure now assembles the fragment (`LCQFTFragment`, module `QtslAux.QuantumAssembly`): an isotone net of local algebras (functoriality); Einstein causality in class-level form — pointwise causally separated diamonds have elementwise-commuting algebras; the time-slice axiom at two tiers — a site-exhaustion surrogate carried as a field of the net, and the genuine grade *proven rather than postulated*: complete initial data plus a reversible mechanism yield Cauchy determinacy at both the algebra and the state grade, with reversibility load-bearing by kernel-checked witness (module `QtslAux.QuantumDeterminacy`); derived-cover separation for the state presheaf; transport of the site, its coverage, the net, and the separation theorems along chronology-respecting order isomorphisms (module `QtslAux.QuantumCovariance`) — which, by the Hawking–King–McCarthy/Malament rigidity cited above, is transport along conformal isometries — with determinacy transported across the same isomorphisms; and a record family whose shadow lands in probability rows. A two-qubit system under an entangling coupling inhabits the whole structure, so no field is vacuous. Two findings earned their way into the structure rather than being designed into it. First, the fragment is a two-tier object of necessity: an entangling mechanism between distant sites acts instantaneously — non-relativistically — so its Heisenberg-evolved observables violate class-level causality at unequal-time spacelike pairs, and no single net can carry both microcausality and the genuine time-slice property at this grade. The kinematic net and the matter data are therefore separate tiers, tied by a shadow equation — the net is the frozen, dynamics-off shadow of the matter data — which is where the locally covariant axioms themselves place dynamics: the time-slice clause is the door through which relative Cauchy evolution and the stress-energy tensor enter [76], both deliberately on the far side of this fragment's fence. Second, the state object is set-valued of necessity: a functorial choice of single states is unrealizable — a theorem of the locally covariant framework [29] — and the replacement that literature adopted, the folium (a contravariant, convex-closed assignment of *sets* of states), is structurally the flat, zero-or-infinite shadow of this chapter's credal bodies: the state doctrine of [section 9.5](#) was independently discovered by mathematical physics, for physics reasons. At matrix grade folium distinctions degenerate, and the degeneration is itself a kernel theorem rather than an admission (every rank-one-positive unital functional on the full matrix algebra is represented by a unique density state), so the toy fragment's real content is contravariance, separation compatibility, and the graded refinement — graded beliefs, walls, partiality — that a flat folium cannot state. The word “fragment” is load-bearing, twice. “Locally covariant” does not mean “the same physics in all spacetimes”: Fewster and Verch proved the stronger property fails for the full class of locally covariant theories [77],

and its repair, dynamical locality, is defined through relative Cauchy evolution — dynamics proper, together with non-surjective embeddings between different spacetimes and functoriality of the assembled fragment along them, are this column's named residues in the closing ledger. And one consequence for the outer storey of the general-relativity paragraph is already kernel-checked at toy grade (module `QtslAux.QuantumOuterStorey`): under a coherent superposition of causal orders — the quantum-switch shape, the same two measurements in the two temporal orders — no record family on the order index exists (the records theorem's contrapositive, its index read as the set of orders), while an orthogonal pointer record classicalizes the index back to an ordinary probability row. Which causal order obtains is a recordable question precisely when something records it — both directions witnessed at toy grade — so the records thesis of this chapter holds unchanged when what superposes is the site itself.

### 9.2.7 Branching Time

A causal order can branch: nothing in the axioms of [section 9.1](#) demands linearity, and a forest of events — histories sharing a past and diverging — is one more causal order, its site delivered by [Definition 9.2](#) like any other (with the degenerate chronology at minimum; a genuinely interior strict chronology exists where the branches are densely ordered and histories diverge along open cuts — a last shared event would defeat the filteredness axiom at the branch point). Branching time therefore needs no column of its own: there is nothing to adopt, and nothing to reject. Two boundaries remain, and a branching order is where both show plainly. The first is that we do not admit nested path quantifiers in the style of branching-time logics like CTL. Our logic ([chapter 14](#), below) *stratifies* into an inner layer of temporal quantifiers along single-timeline records, and an outer layer regarding the imprecise-probabilistic ensemble of such records. The second is a boundary of canonicity rather than of expressibility: treating a *quantum* system as branching-time — an Everettian forest as its causal order, branch weights as a measure — is non-canonical relative to the universal-wavefunction reading, because branch structure is decoherence-emergent and decomposition-dependent, so a certificate over a branching order would certify a claim about a *chosen* decomposition. (The asymmetry grounding this judgement is kernel-checked in the quantum paragraphs above: records force consistency of a branch family, and consistency alone supplies no records.) That is why the open-quantum column above enters through the master-equation flow over an ordinary site, with measurement records as classical stochastic processes read by record-level probabilities.

### 9.2.8 The Logic-Site Contract

The toolkit does not, at present, *adopt* a nonclassical site: no present application demands one, and the classical instantiation must never pay for the option. What it adopts is a contract — six freedoms the artefact formats keep, so that the site parameter can later be exercised without restaging a single classical artefact:

- F1. No absolute-time fields.** Time enters manifests and specifications only as durations, per-mechanism clocks, and clock morphisms with rate/jitter bounds; never a timeline table, never a timestamp.
- F2. The checker never sees the site.** All site content stays on the semantic side of the certification interface; obligations are polynomial (or operator) rows with no time-shaped vocabulary.
- F3. Total-order consumers are flagged.** Début, until, and cofinality clauses are stated as record-indexed, so a site change re-indexes rather than re-defines them. One such re-indexing is realized rather than merely flagged by the record carrier of [section 9.4](#): endpoint consumers become germ consumers. Over the interior coverage a window's own boundary stages are covered by nothing — data pinned to an outer seam is exactly what translation-homogeneity forbids, the same demotion that turns absolute time into the internal clock — so a clause that consults a window's endpoint re-indexes as a *germ* clause at the seam: a clause about the behaviour's germ there rather than its value there. The endpoint itself survives, like absolute time, as presentation data of an anchored tower of windows (a family sharing a fixed initial stage, whose shared seam survives every restriction), not as site data.
- F4. Mechanism profiles stay an open enumeration.** A new dynamics family (an open-quantum generator, say) is additive; no existing profile recompiles.
- F5. Clock morphisms keep the rate-relation form.** The wiring datum is bounds on  $d\sigma/d\tau$  plus jitter, never a schedule table in absolute time; clock-*rate* corrections (gravitational and velocity time

dilation) then arrive as *values* in an existing field, not as a schema change. The named exception: signal-*path* obligations — Sagnac terms, null-propagation time of flight — are not per-clock rate data; they need ephemeris or worldline data plus a propagation constraint, still ordinary classical model data in a named frame, but data the rate-relation form does not carry.

- F6. Duration and tangency stay ambient.** Mechanisms present tangency as doctrine-specific generator data (drift, diffusion, jump, or operator rows) and duration as rational constants; no artefact names either structure as an object.

Against the only metric that matters for a toolkit — does the classical user pay? — the verdict, costs counted, is: nothing. No extra field, no extra obligation, no slower check, on either generalization column. The cost of *adopting* a column when an application arrives is a named metatheory ledger, several of whose items are already discharged ahead of any adoption — all kernel-checked in this repository (`QtslAux.DiamondSite`, `QtslAux.OpenQuantum`): for the causal-diamond column, the coverage lemma, the thickness iff, the clock-map checks, and the time-inhomogeneity item's clock-adjunction core; for the open-quantum column, the bounded-generator hypothesis's transport theorem. What remains owed there is the site-generic transport of the extension theorems — split by the carrier of [section 9.4](#) into a presentation-shaped half that transports along inverse-image functors because presentations by generators and relations pull back (geometricity makes that half free in principle) and an analytic half (choice-invoking or point-set-surgical constructions) that runs objectwise over finite-duration windows, where the classical proofs apply unchanged, so the audit is per window class, not per theorem per site — together with the probabilistic time-inhomogeneity lemma's projective-limit step and the open-quantum event/record transport theorem, each named in [section 9.13](#).

## 9.3 Records

What lives on a window is an observation history over its stages: a *record*. The definition arrives in two steps — first along a single timeline, the object every temporal clause of the specification logic actually reads, and then over a general causal support, where a record is a coherent bundle of timeline records, one along each of its worldlines.

Along a single timeline a record is a totally ordered history of observations: the trajectory of a classical composite read on the global timeline; a component's local history read against its own clock; the proper-time worldline of a relativistic clock; the outcome sequence of a monitored quantum device. What these share — and what the specification logic consumes — is a totally ordered time axis *carrying duration*: the order alone is not enough — two of the three clause families below consume more than it: one does arithmetic on elapsed time, and the *début*'s infimum must exist in the record's own axis. The *début* of a region ( $\tau_E = \inf\{t : x_t \in E\}$ ), the “no visit before  $\tau$ ” clause of an until operator (and its metric variant's window  $U_{\leq T}$ ), the cofinal visits of a recurrence condition: each is well-defined along any record equipped with the ordered time-and-duration structure of [Definition 9.6](#), and none needs to know how that record sits inside a larger geometry of time.

**Definition 9.6 (Record).** A *record* is a tuple  $R = (T, \leq, \delta, \mathcal{O}, x)$  consisting of the following data.

1. *Stages.* A nonempty set  $T$ , totally ordered by  $\leq$ , whose order is *conditionally complete*: every nonempty subset of  $T$  that is bounded below has an infimum in  $T$ .
2. *Duration.* A *duration functor*

$$\delta: \{(s, t) \in T \times T : s \leq t\} \longrightarrow [0, \infty]$$

satisfying

$$(R1) \quad \delta(t, t) = 0 \text{ for every } t \in T;$$

$$(R2) \quad (\text{additivity along the order}) \quad \delta(s, u) = \delta(s, t) + \delta(t, u) \text{ whenever } s \leq t \leq u \text{ in } T.$$

1. *Observations.* An *observation space*  $\mathcal{O}$  — a set, required to be a measurable space whenever the record enters the denotation stack of [Definition 9.15](#) — and an *observation map*  $x: T \rightarrow \mathcal{O}$ , written  $t \mapsto x_t$ .

Equivalently, and more precisely: a duration functor is a *functor*  $(T, \leq) \rightarrow \mathbf{B}[0, \infty]$  from the stage order, read as a thin category, to the delooping of the additive monoid  $([0, \infty], +, 0)$  — functoriality on composites is (R2), preservation of identities is (R1). (Not an *enrichment*: a category enriched in  $[0, \infty]$  is a Lawvere metric space, whose composition law is the triangle *inequality*; duration along a timeline is additive on the nose.) From (R1)–(R2),  $\delta$  is antitone in its first endpoint and monotone in its second:  $s' \leq s \leq t \leq t'$  implies  $\delta(s, t) \leq \delta(s', t')$ . Two non-requirements are deliberate, and both do real work. *Strict positivity is not required*: distinct stages may be separated by zero duration (instantaneous transitions consume none, which is how hybrid records carry reset events). *Finiteness is not required*:  $\delta$  may take the value  $\infty$  on pairs separated by an unbounded extent.

For a subset  $E \subseteq \mathcal{O}$  (measurable, when  $\mathcal{O}$  is a measurable space), the *hitting set* of  $E$  is  $T_E := \{t \in T : x_t \in E\}$ , and the *début* of  $E$  is

$$\tau_E := \inf T_E \in T \cup \{+\infty\},$$

defined to be the infimum in  $T$  when  $T_E$  is nonempty and bounded below — which conditional completeness guarantees to exist — and the formal top element  $+\infty$  (adjoined to  $T$ ) when  $T_E = \emptyset$ . The début is deliberately *partial*: for a nonempty hitting set unbounded below (possible only in a record with no start), no value is assigned, and every satisfaction clause that consumes a début carries the bounded-below proviso. When  $T$  has a least element (a record with a start), every nonempty subset is bounded below and the début of every region is defined.

The stage set  $T$  is free data here and moored below: for a record over a window of the site (Definition 9.8), the stage sets to which this definition applies are the *maximal chains* of the record's support in the window's stage poset  $|W|$  — the site's (T2) data, under the induced order — with  $\delta$  not chosen but inherited from the site's (T3) duration structure on that timeline. Maximality is load-bearing on both sides: the maximal chains cover the support (so the bundle of timeline records misses no stage), while a restriction to a *non*-maximal chain need not satisfy this definition at all — omitting a stage can delete an infimum and break conditional completeness. The definition is stated free-standing so that the logic's single-timeline clauses consume exactly this structure and no site geometry — the record tier's face of the site contract's second freedom.

A thermostat log makes the data concrete: stages  $T = \{0, 1, \dots, n\}$ , one sample per second, with  $\delta(m, m') = m' - m$  seconds and observations the measured temperatures. For the region  $E = \{x : x \geq 30\}$  the hitting set collects the hot samples, and the début  $\tau_E$  is the first hot second — or  $+\infty$ , if the log never gets hot. A hybrid version of the same log carries a controller reboot as two distinct stages separated by zero duration, which is exactly what the definition's first non-requirement permits.

*Remark 9.7* (The three record-indexed clause families, and what each consumes). The satisfaction clauses of the specification logic that consume a record's temporal structure sort into exactly three families, and the data of Definition 9.6 are precisely what makes each well-defined. A bare total order does *not* suffice.

1. *Débuts* ( $\tau_E = \inf\{t : x_t \in E\}$ ) consume conditional completeness of the order (item 1): in a general totally ordered set a nonempty bounded-below hitting set need not have an infimum, and the début clause would then have no referent.
2. *Metric-bounded windows* (the deadline operator  $F_{\leq \ell}$  and metric until clauses) consume the duration functor (item 2): the window of extent  $\ell$  anchored at  $t$  is  $\{s \in T : t \leq s, \delta(t, s) \leq \ell\}$ , and no such set is definable from the order alone.
3. *Cofinal recurrence* (“ $x$  visits  $E$  cofinally”: for every  $t \in T$  there is  $s \geq t$  with  $x_s \in E$ ) consumes only the order, through its cofinal structure; it is definable in any total order and needs neither infima nor durations.

Both standard instantiations satisfy all hypotheses at no cost: discrete records ( $T \subseteq \mathbb{N}$ ,  $\delta(m, n) = n - m$  or a per-step duration sum) are well-ordered, hence conditionally complete; interval records ( $T$  a real interval,  $\delta(s, t) = t - s$ ; more generally proper time along a worldline) are conditionally complete by completeness of  $\mathbb{R}$ .

Division of labour, recorded here because the site supplies the other half: *the record carries the duration structure, while the mechanism carries the tangency structure*; the two meet in the generator row, where a tangency-typed operator is compared against an inverse-duration-typed scalar.

Definition 9.6 is stated along one timeline, and on the classical site — where a window's stages are totally ordered, so any support lies along one timeline automatically — it is the whole story. Over a general

spacetime site it cannot be: two facts force a wider notion, and between them fix its shape. The first fact is geometric. In the Minkowski site a chronologically thick diamond's stage space contains causally incomparable pairs — kernel-checked as a witness in the canonical unit diamond, over any normed space of positive dimension (`QtslAux.DiamondTopology: minkowski_diamond_spacelike_pair`) — so a record supported on one timeline cannot span such a window: the restriction of a field to a diamond, the honest “trajectory” of the hyperbolic column, is not a timeline object, and total stage order stands revealed as the foliated  $(0+1)$ -dimensional shadow — the same diagnosis Remark 9.5 gives the classical site itself. The second fact is metric, and it is what makes the wider notion *forced* rather than designed. In a relativistic order the natural duration between causally related events — the Lorentzian distance, the *supremum* of proper time over the causal curves joining them — satisfies the *reverse* triangle inequality: it is superadditive, so the additivity axiom (R2) fails for any single global valuation built from it. What is additive is a different functional — the proper-time integral along a *fixed* worldline, one functional per timeline — so duration must enter timeline by timeline: precisely the form the site's duration structure (T3) already takes, the classical definition's global  $\delta$  being its one-timeline shadow.

**Definition 9.8** (Record over a window). Let  $W$  be a window of a structured spacetime site, with stage poset  $|W|$  and duration functors  $\delta_\gamma$  on its timelines (T2–T3 of Definition 9.4). Let  $R_0 = (T_0, \leq, \delta_0, \mathcal{O}, x)$  carry the data of Definition 9.6 per maximal chain as below, together with a monotone *stage map*  $m: T_0 \rightarrow |W|$  whose fibers are the same-instant stacks (order-convex,  $\delta_0$ -null) and which carries each maximal chain of  $T_0$  onto a timeline of  $W$  with  $\delta_0 = \delta_\gamma \circ (m \times m)$  there. The pair

$$R = (R_0, m)$$

is a *record over  $W$*  when, for every maximal chain  $\gamma_0$  of  $T_0$ , the restriction  $(\gamma_0, \leq, \delta_0, \mathcal{O}, x|_{\gamma_0})$  is a record in the sense of Definition 9.6.

A record over a window is a coherent bundle of its own worldline shadows: every maximal-chain restriction is a classical record, matched onto the window's timeline against the site's own valuation — and the record's carrier presentation is the closed set  $\text{cl}\{(m(t), x_t)\}$  — single-valued exactly off the stacks and jump instants, multivalued at them, with single-valuedness a certified stratum rather than a membership condition (the general-support countermodels of the closing ledger force the same demotion independently). (Maximal chains pass through every stage of the support — Hausdorff's maximal principle, part of the ambient classical mathematics — so the bundle covers the record; and the restriction to a *non*-maximal chain need not be a record, conditional completeness not being hereditary, which is why the definition tests exactly the maximal ones.) The record itself is site-relative data: the pair  $(T, x)$  carries no duration, and its timeline shadows become classical records only against the window's own valuations  $\delta_\gamma$ , supplied by (T3) before any clause runs. The clause families of Remark 9.7 relativize accordingly, timeline by timeline: débuts and metric-bounded windows evaluate on the shadows  $(\gamma, \leq, \delta_\gamma, \mathcal{O}, x|_\gamma)$ , where conditional completeness and (R1)–(R2) hold by definition, and cofinal recurrence reads the support's own order directly. Each shadow is a free-standing classical record, and the clauses read nothing but the shadows — duration reaches the logic packaged inside them, and the coverage, the site structure the invariant of (T1) fences off, enters nowhere. (Which timelines a claim quantifies over — some worldline through the record, or every one — is spec-level structure one storey up, not record data; none of the three clause families ever needed a global début, and should one ever be wanted, its referent is the entry *antichain* of a hitting region rather than an infimum stage.)

*Conservativity*: over the classical site a window's stages are totally ordered, so every subset is a chain and a stack-free record's support ( $m$  injective) has exactly one maximal chain — itself — and Definition 9.8 asks exactly that  $(T_0, \leq, \delta_0, \mathcal{O}, x)$  be a record in the sense of Definition 9.6 against the window's own valuation  $\delta_0(s, t) = t - s$  read through  $m$ . That is precisely the valuation the classical artefacts' records carry (Remark 9.5), so those records *are* records over their windows, with nothing re-indexed and nothing added: over a totally ordered window the two definitions coincide. *Two support classes, one definition*: a record supported on a single chain is a *worldline probe* — an observer's history through the window — while a record with chronologically thick support is a *field restriction*, a PDE trajectory over a diamond being the graph of the field over the diamond's interior; and reading a record along one of its timelines — the observer's act — is literally the definition's restriction component. A clock map, in particular, remains what the diamond column says it is: a way of *reading* a record along a worldline, never part of what a record is.

The organizing principle of the temporal layers — call it the *records thesis* — is the resulting division of labour:

Path formulas are evaluated along records, and consult only the structure a single record carries — its order and its durations. The site governs how records glue into a System’s trajectory space, and only that: its cross-record geometry enters no satisfaction clause. The denotation says what lives on the glued space. Composition of Systems is summation of their beliefs, each transported to the joint records along the wiring: the composite’s belief is the sum of its parts.

Each clause of the thesis bounds the blast radius of the others. Because satisfaction consults only record-level structure, generalizing the time base cannot silently change what any specification means; the three satisfaction clauses that consume the record’s order — *début*, *until*, *cofinality* — are flagged in the semantics as *record-indexed*, so that a new site re-indexes them rather than re-defining them (a re-indexing Definition 9.8 realizes: over a general support they evaluate along maximal chains). Because the denotation is a measure-like object *over* records rather than a new kind of record, the imprecise apparatus of section 9.5 transports along the record direction by construction — with the caveat stated: its extension theorems are proven on the discrete-time record poset, and each new site owes the transport of exactly those theorems to its own record structure (a named obligation of the logic-site contract of section 9.2, not a free consequence of the flagging). And the thesis has a sharp outer boundary, drawn in subsection 9.2.7: quantification *across* records is admitted only at the specification logic’s outer layer, as imprecise-probabilistic claims about the ensemble — nested path quantifiers in the style of branching-time logics have no inner-layer home, by the same stratification.

One reading of records is fixed here because everything in section 9.4 depends on it: the *speed-bounded* records over a window of the site — those whose difference quotients, along each timeline of the support, lie in a fixed ball of the tangency’s action bundle, the single metric hypothesis the record layer keeps — are read *as their graphs*, closed subsets of a stage-times-state ambient, and the class of such records over a window carries the Fell topology on closed sets. (A general record — of Definition 9.6 or of Definition 9.8 — carries no topology and no closed-graph condition; the graph reading is a property of the speed-bounded class, not of the notion.) Under that reading the record class over each window — at the classical stratum, where a support is a timeline — is compact, and gluing along the interior coverage — directed open covers at fixed state fibre — is a homeomorphism onto a projective limit. The kernel receipts behind those sentences live at that stratum; over general supports the graph reading transports objectwise verbatim, while compactness rests on closedness of the record locus — which does not bundle per timeline: the closed object over thick supports is an interior-pair relaxation of the record class, its boundary conditions surviving as certified strata — an obligation stated with its two site hypotheses in the closing ledger, not a free consequence. The reading is developed, with its kernel receipts, in section 9.4; nothing in the satisfaction clauses above changes under it, which is the records thesis doing its job.

## 9.4 The Record Carrier: Fell Hyperspaces over the Site

The records of a window live in a definite space — the strata to follow quantify over exactly it. Per section 9.3, a speed-bounded record over a window is its graph, a closed subset of a stage-times-state ambient, and the record class carries the Fell topology on closed sets. The Fell topology is moreover *the* hyperspace topology that glues along directed open covers — the descent theorem below, kernel-checked — so the record carrier is a sheaf of compact spaces for exactly the interior coverage the site already adopted (whose covers are directed by pair-filteredness), at fixed state fibre.

### 9.4.1 The Carrier, and Its Descent

**The ambient and the carrier.** Fix a window  $W$ . The *ambient* is

$$A(W) := \mathring{S}(W) \times \mathcal{V}^+(W),$$

the *open interior* of the stage space (the design decision justified by the seam analysis below) times the state fibre of section 9.2 with its cemetery adjoined — the one-point operation applied here, at the tier that consumes its output; by (T5) and the fibre commitments,  $A(W)$  is locally compact, second-countable

Hausdorff, the compactified factor compact metrizable outright. The *carrier* over  $W$  is

$$\mathbb{H}(W) := \text{CL}(A(W))_{\text{Fell}},$$

the space of *all* closed subsets of the ambient — the empty set included — under the Fell topology [75]: the topology generated by the classes  $\text{Hit}(V) = \{F : F \cap V \neq \emptyset\}$  for  $V$  open and  $\text{Miss}(K) = \{F : F \cap K = \emptyset\}$  for  $K$  compact. Restriction along a site morphism  $u: W' \rightarrow W$  is clip-then-push:

$$\rho_u := (- \cap (|u|(\dot{S}(W')) \times \mathcal{V}^+(W))) \circ (\mathcal{V}^+(u))_*,$$

clip to the open sub-band, then push the state coordinate forward along the (proper) restriction of the state sheaf. Two lemmas make every  $\rho_u$  Fell-continuous, and each is short enough to give whole. *Clip-to-open is Fell-continuous*: for  $U \subseteq Y$  open, under  $F \mapsto F \cap U$  the preimage of  $\text{Hit}(V)$  ( $V \subseteq U$  open) is  $\text{Hit}(V)$ , and the preimage of  $\text{Miss}(K)$  ( $K \subseteq U$  compact) is  $\text{Miss}(K)$  — both subbasic. *Pushforward along proper continuous maps is Fell-continuous*: for  $f: Y \rightarrow Z$  proper continuous into a locally compact Hausdorff  $Z$  (so images of closed sets are closed), under  $F \mapsto f[F]$  the preimage of  $\text{Hit}(V)$  is  $\text{Hit}(f^{-1}V)$  (open, by continuity) and the preimage of  $\text{Miss}(K)$  is  $\text{Miss}(f^{-1}K)$  (compact, by properness). The two subbasis families split the work exactly — continuity feeds the hit face, properness feeds the miss face. The same split carries the descent theorem:

**Theorem 9.9** (Fell descent over directed opens). *Let  $Y$  be a topological space and  $\{U_i\}_{i \in I}$  a directed family of open subsets (any two contained in a third) with union  $Y$ . Then the clip maps  $\rho_i: \text{CL}(Y) \rightarrow \text{CL}(U_i)$  induce a homeomorphism*

$$\text{CL}(Y) \xrightarrow{\cong} \varprojlim_i \text{CL}(U_i)$$

*onto the space of compatible families, the limit carrying the limit (initial) topology.*

*Proof.* Bijectivity: injectivity is  $F = \bigcup_i (F \cap U_i)$ ; for surjectivity a compatible family  $(F_i)$  glues to  $F := \bigcup_i F_i$ , closed because closedness is local, with  $F \cap U_i = F_i$  (a point of  $F \cap U_i$  lies in some  $F_j$ ; directedness gives  $U_k \supseteq U_i \cup U_j$ , and  $F_k \cap U_i = F_i$  collects it). Topology: each  $\rho_i$  is continuous by the clip lemma, so the Fell topology refines the initial topology; conversely every Fell-subbasic class of  $\text{CL}(Y)$  is pulled back from a level —  $\text{Hit}(V) = \bigcup_i \rho_i^{-1} \text{Hit}(V \cap U_i)$ , since a closed set hits the open  $V$  iff it hits some  $V \cap U_i$ , and for compact  $K$  directedness places  $K$  inside a single  $U_i$ , whence  $\text{Miss}(K) = \rho_i^{-1} \text{Miss}(K)$ .  $\square$

Both subbasis families again carry the theorem, and this time the split is the whole of it: *hits are local* (an open set is the union of its cover-traces) and *misses are compactly supported* (a compact miss-parameter lands inside one cover member, by directedness). The Vietoris topology fails the second half — a miss-of-closed parameter need not land in any cover member — and the refuting fixture shows the miss face sharp: over a directed cover of  $\mathbb{N}$ , the miss class of a closed noncompact parameter fails to be open in the limit topology, by a witness (a far-enough singleton, whose clips agree with the empty record's on any finite set of levels) that defeats every hyperspace topology carrying the closed-miss upper face. Of the two candidate miss faces, then, only the compact one descends, and Fell's two design decisions (hit-of-open, miss-of-compact) are respectively the local-character axiom and the finite-support axiom of a sheaf-ready topology. Interior covers of a window are pair-filtered (the kernel-checked bicontinuous-poset lemma of section 9.2) and their interiors union to  $\dot{S}(W)$ ; crossing with the covered window's own state fibre preserves both properties. Hence:

**Proposition 9.10** (The carrier is a sheaf of compact spaces). *Consider a cover of the site's coverage satisfying the two hypotheses the kernel theorem consumes: its members' stage interiors, embedded in the covered window, form a directed family of open subsets whose union is the window's interior (interior coverages supply this — pair-filteredness is directedness, and openness and exhaustion are the coverage's construction); and its members' ambients carry the covered window's state fibre (every cover of the classical instantiation; every cover under a state sheaf constant on the window being covered). For every such cover,  $\mathbb{H}(W) \rightarrow \varprojlim_{W' \in \text{cover}} \mathbb{H}(W')$  is a homeomorphism, and on that stratum  $\mathbb{H}$  is a sheaf on  $(\mathcal{T}, J)$  valued in compact Hausdorff spaces. (A site whose coverage violated the first hypothesis would owe its own descent theorem — the kernel fixtures below show both directedness and the miss face sharp — and under a genuinely varying state sheaf the restriction legs compose the clip with a proper pushforward, whose sheaf property is prose-grade design, not an instance of the kernel theorem.)*

Compactness arrives with no hypotheses at all:  $\text{CL}(Y)$  under Fell is compact for *every* ambient  $Y$  (an Alexander-subbasis argument), Hausdorff when  $Y$  is locally compact Hausdorff, and equal to the Vietoris

hyperspace on compact Hausdorff ambients. Over an unbounded ray ambient, compactness of a record class is a theorem with hypotheses; over the site it is a corollary of closedness in a hyperspace that is compact for free. Nothing of Fell's noncompact machinery is thereby discarded: it is *localized*. In the classical instantiation windows have finite duration, so the unbounded horizon vanishes from every object; what stays noncompact per window is the open interior (seams) and the fibre (escape), and the compact-miss face polices both by one mechanism — the empty set is a closed point of every  $\mathbb{H}(W)$ , isolated only over a compact ambient (a zero-duration window has empty interior and carries the one-point trivial carrier; every nondegenerate window's open-interior ambient is noncompact), and over the nondegenerate windows it is the limit of records draining out of every compact: total escape, escape out a seam, and escape to  $\infty_W$  are boundary members of the carrier, rather than pathologies excluded by fiat.

**The seam fork, and why sheafification decides it.** The ambient uses the *open interior* of the stage space, and this is forced, not chosen. Restriction to a *closed* subwindow fails Fell-continuity at records with a jump exactly on the seam: a family of records with jumps at times  $u' + \frac{1}{n}$  converges in Fell to the record jumping at  $u'$ , but the closed-clip images stay at Hausdorff distance  $\geq 1$  forever, because the limit's clip carries a zero-duration post-jump stage on the seam that no approximant's clip carries. (The witness is hybrid-only: for pure flows under the speed bound, closed clipping is continuous; the fork is exactly the price of jumps. It is kernel-checked as a refuting fixture beside the clip lemma.) The resolution is that the site had already made the decision: the closed-window record presheaf is not a sheaf — a matching family over a window's interior cover determines the record on the union of the members' interiors, which is the window's open interior, and *nothing at the outer seams* — and its sheafification is precisely the open-interior carrier above. Read with the site's own glosses this stops being a technicality: the site quotients translation, so a window's outer seams have no absolute identity — data pinned to this window's own boundary is exactly the data translation-homogeneity forbids. Sheafification forgets the seams because homogeneity requires it; seam data returns in the anchored-tower presentation (a family of windows sharing a fixed initial stage), in the same movement that returns absolute time as the internal clock, which is the germ row of the logic-site contract (F3).

One coverage, three independent derivations, no shared premises: the interior coverage is simultaneously the behavioural choice (Schultz and Spivak omit endpoint gluing for composability of behaviours), the continuity choice (closed clipping is discontinuous at seam jumps), and the descent choice (Theorem 9.9 needs directed opens). A choice made for behavioural reasons is forced again by continuity and a third time by descent.

## 9.4.2 The Record Locus

**The record locus is a closed subsheaf.** Within each  $\mathbb{H}(W)$ , the *record locus*  $\mathbb{R}(W)$  comprises the closed sets that are graphs of speed-bounded records over relatively closed sub-timelines of the window interior — the classical, single-timeline locus throughout this paragraph; over the general supports of Definition 9.8 the closed object is an interior-pair relaxation, per the ledger's named obligation — unanchored and lifetime-windowed: records may begin and end strictly inside the window (early stop and late start are membership, not defect, in a translation-quotiented site), the empty record is a member, and the class is Zeno-inclusive: Zeno-boundary points are themselves honest records (a Zeno stage domain, lexicographically ordered, is conditionally complete — its infima land on the lowest branch of the stack), and locally finite *event* structure is a certified stratum inside the carrier — closed (a continuous image of the compact parameter class; equivalently bounded alternation between separated regions, a class built from time-ordered finite hit demands) and disjoint from the chatter boundary — carried by the crossing-budget row family, not the locus's definition: the budget was never a compactness hypothesis; its remaining job is mechanism-side progress — a ghost storm (state-invisible events accumulating) stalls a System without casting a shadow, which is exactly why liveness rows consume the budget and safety rows never did. The structure theorem factors through a generic principle: call a family of per-level loci  $R_i \subseteq \text{CL}(U_i)$ , with ambient locus  $R_0$ , *local* when membership in  $R_0$  is equivalent to membership of every clip in every  $R_i$ . A levelwise-closed local locus is closed (an intersection of clip-preimages of closed sets, by clip-continuity), hence *compact for free* in the hypothesis-free compact hyperspace; compatible families levelwise in the loci glue into the ambient locus; and the descent homeomorphism restricts to a homeomorphism of the ambient locus onto the levelwise-locus subspace of the projective limit — the closed-subsheaf statement. The record instantiation discharges the two obligations: the speed-graph condition is closed (a violating pair has a positive defect

margin that two hit demands preserve — pure hit face, no compactness consumed), and it is local over directed covers, directedness entering at exactly one step (a violating pair’s two points must meet in one cover member). All of this is kernel-checked, together with the sharpness fixtures that bound it: the speed bound cannot be dropped or existentially absorbed (a steepening family of affine graphs Fell-converges to a vertical fibre, which is no graph at any speed — so the bare-graph locus and the all-speeds union are not closed), and directedness is essential at statement level (over a nondirected two-member cover there is a two-point set, every clip of which is a record, that is no record — levelwise record-hood does not imply record-hood, and compatible levelwise records can glue to a non-record). The arc reading is also a theorem rather than a gloss: membership in the speed locus over a product ambient is equivalent to being the graph of a Lipschitz arc on a closed sub-timeline, with relative closedness of the domain *derived* — a converging sequence of domain points has its states Cauchy by the speed condition itself, completeness of the state fibre collects the limit, and closedness of the graph does the rest.

*Remark 9.11* (Mechanization status of the carrier). Kernel-checked, in the semantic-universe strand of the toolkit’s proof-artefact repository (modules named per statement; the receipts conventions are [section 9.13](#)’s): the Fell topology, its hypothesis-free compactness, Hausdorffness over locally compact ambients, and the polarity lemmas of the hit and miss faces (SuFunctor.Universe.FellTopology, including FellClosedS.compactSpace with no hypotheses on the ambient, and fell\_eq\_vietoris on compact Hausdorff ambients); clip-to-open continuity with its mutant fixtures, and proper-map pushforward continuity (SuFunctor.Universe.FellRestrict: continuous\_restrictOpen, continuous\_image\_of\_isProperMap); the seam witness (SuFunctor.Universe.FellSeamWitness, refuting closed-band clipping through the zero-duration post-jump stage); Theorem 9.9 as FellClosedS.projLimHomeomorph with the glue-clip roundtrips and continuity in both directions (SuFunctor.Universe.FellDescent), together with the sharpness fixtures (a nondirected cover on which the canonical map fails surjectivity; the Vietoris comparison on which the miss face’s compact support fails); the record locus (SuFunctor.Universe.FellRecordLocus: the generic local-locus package IsLocalLocus.isClosed/isCompact/glue\_mem/homeomorph, the speed locus speedLocus with isClosed\_speedLocus, isSpeedGraph\_iff\_forall\_clip, speedLocusHomeomorph, membership one-liners including bot\_mem\_speedLocus and isLocallyClosed\_speedLocus, and the arc reading isSpeedGraph\_iff\_exists\_lipschitzOnWith) with its refuting fixtures (SuFunctor.Universe.FellRecordWitness: the steepening family, the vertical fibre, the nondirected specimens); and the one-point compactification, packaged as a hyperspace correspondence: adjoining the point at infinity is a homeomorphism  $CL(Y) \cong \{B \in \mathcal{K}(Y^+) : \infty \in B\}$  (SuFunctor.Universe.FellOnePoint), holding for arbitrary ambients at the Fell stratum — reading the upstairs topology as Vietoris consumes local compactness and Hausdorffness of the ambient (topology\_onePoint\_eq\_vietoris), which every (T5) ambient supplies — so the correspondence carries the Fell form of a noncompact ambient into the nonempty-compacts Vietoris presentation the class stratum of [section 9.7](#) is stated over. The scope boundary: the mechanized record locus is the pure-flow (single-timeline) stratum; the hybrid (multivalued-instant) stratum rides the chart route — the shadow of the compact parameter class, with alternation-bounded classes closed by hit-face arithmetic — and its mechanization is an obligation recorded in [section 9.13](#).

### 9.4.3 Records Determine Laws

**The capacity presentation.** The denotation stack of [section 9.5](#) puts measures — and beliefs over measures — on the record carrier, so the carrier owes the stack a determination principle: which observations pin a law? The answer is certificate-shaped. Call a family of *hit-and-miss generators* over an indexed open basis  $B: \iota \rightarrow \text{Open}(Y)$  with compact closures the classes

$$\nabla_B(\text{hits}, \text{misses}) = \left\{ F \mid (\forall i \in \text{hits} : F \cap B_i \neq \emptyset) \wedge (\forall j \in \text{misses} : F \cap \overline{B_j} = \emptyset) \right\},$$

for finite index sets *hits*, *misses*. These generators form a topological *basis* of the Fell hyperspace; with countably many basis indices the hyperspace is second countable, and the Fell hyperspace of a (T5) ambient is therefore *compact metrizable*. The determination principle:

**Theorem 9.12** (Capacity presentation). *Over a locally compact Hausdorff ambient with a countable open basis of compact closures, two finite Borel measures on the Fell hyperspace that agree on every hit-and-miss generator are equal. (The generator family is a  $\pi$ -system — intersecting generators unions their index sets — containing the whole*

space as the empty generator, and it generates the Borel  $\sigma$ -algebra because the generators form a countable basis; the empty generator is what subsumes total-mass agreement, so the statement carries no separate mass hypothesis.)

This is the determination half of the Choquet–Matheron theorem for random closed sets [175], on the Fell carrier, in a form a checker row can consume: a *distinctness* certificate is one generator — two finite sets of basis indices — plus two evaluations, and identity is the countable schema over the enumerated generators. With the observation basis below, the indices are rational data, so laws on the record locus are determined by their evaluations on a countable, *rationaly indexed* family of hit-and-miss observations: records determine laws, with the observations — though not the evaluated measures — exact data of the kind the certificate stratum consumes. Two boundary facts are kernel-checked beside the theorem and are content, not caveats: the compactness of the miss parameters is what makes the generators open at all (over any noncompact ambient, the miss class of the whole space is not Fell-open — the escape specimen again); and the hit face *alone* does not determine, at the frame level — there are two Scott-continuous functionals on the opens of the hyperspace agreeing on the entire hit-generated (lower-Vietoris) topology and differing on a compact miss class. Escape mass is exactly what the hit face cannot see; the miss face exists, at determination level, to count escape. (Classically, hit-only determination survives via  $\sigma$ -algebra complements and a pinned total mass; frames have no complements, and the fixture is that difference made a theorem.)

*Remark 9.13* (Mechanization status of the capacity presentation). Kernel-checked, module `SuFunctor.Universe.FellCapacity`: `nablaGen`, `isTopologicalBasis_nablaGen`, the second-countability instance, Theorem 9.12 as `measure_ext_of_nablaGen`, the separation corollary `exists_nablaGen_measure_ne`, the Scott-continuous frame form `scottContinuous_ext_of_nablaGen`, and the two boundary fixtures `not_isOpen_disjoint_univ` and `exists_scottContinuous_eq_on_lower_ne`. The full localic Choquet–Matheron statement — the frame of the hyperspace locale presented by these generators, with continuous valuations determined by generator values — is kernel-checked as well, in the point-free library: the presented frame is built as the free frame on the hit-and-miss data semilattice, quotiented by the least nucleus forcing the transposed hit-and-miss laws (`Pointfree.Frame.Presentation`, `Pointfree.Frame.HyperspacePresentation`), and on it two Scott-continuous valuations with finite generator values agreeing on every  $\nabla$ -generator are equal, distinct ones separated by a single generator (`Valuation.ext_of_nabla`, `Valuation.exists_nabla_ne`). The engine (`Pointfree.Valuation.ext_of_generators`) is frame-general — any frame carrying a meet-closed, join-generating generator family — so it applies to the presented frame at any relation set and to the spatial frame of opens alike (`Valuation.ext_of_isTopologicalBasis`): no points, no countability, no  $\sigma$ -algebra, and the finiteness hypothesis sharpened from total mass to generator values — modularity manufactures from generator values the finite-join agreement the Scott-continuous form above hypothesizes. What was deliberately not claimed remains so: the existence half of Choquet’s theorem, capacity functional to law, is not claimed — the stack consumes determination only.

**The observation basis.** The basis the generators range over is fixed once. For the toolkit’s actual ambients — stage intervals times  $\omega$ -semialgebraic state fibres, the live part  $\mathring{S}(W) \times V(W)$  presented inside a real coordinate space and the cemetery adjoined by the one-point operation — it is the family generated under finite unions and intersections by two rational families. On the live part: rational-coefficient semialgebraic opens traced onto  $\mathring{S}(W) \times V(W)$ , refined to the subfamily with compact closures (rational opens are a base of the coordinate space, and tracing preserves countability, lattice closure, and the base property). At the cemetery: products  $J \times (\mathcal{V}^+(W) \setminus K_n)$  of a rational stage interval  $J$  with compact closure in  $\mathring{S}(W)$  and the complement of a member of a fixed rational compact exhaustion  $K_0 \subseteq K_1 \subseteq \dots$  of the fibre — an exhaustion exists because a locally compact, second-countable fibre is  $\sigma$ -compact, and its members can be taken carved by rational data (traces of closed rational balls suffice). The result is countable, closed under finite unions and intersections, and a base of the topology of every such ambient: at live points the traces already form a base, since the live fibre is open in its compactification; at points over  $\infty_W$  the exhaustion complements are cofinal among neighborhoods, since every compact subset of  $V(W)$  lies in some  $K_n$ ; and closures stay compact ( $\bar{J} \times \mathcal{V}^+(W)$  is compact — the compactified fibre is compact by construction). This is also the honest shape of what a certificate can check near escape: a basis neighborhood of the cemetery says exactly “eventually outside  $K_n$ ” — finite rational data, with no carving of the point  $\infty_W$  demanded. A general (T5) ambient, which need not carry any coordinate presentation, uses an abstract countable basis of compact closures, which local compactness and second countability supply; the capacity theorem

consumes only that. Two consequences. First, the record-class observation domain is insensitive to the state-space dial of [section 9.2](#): the fibre carving class and the test-region class are independent dials, and the  $\omega$ -semialgebraic upgrade moves only the former — test regions stay rational-semialgebraic, which is where certificate rows need them, since a certificate row refuting  $\text{Hit}(V)$  consumes  $V$ 's polynomial presentation. Second, the hit-and-miss generators over this basis are precisely the *crescent* shape the class stratum of [section 9.7](#) builds its spec classes from — one closed demand cut by finitely many open escapes — so the carrier's determination principle, the checker's test regions, and the spec logic's atoms speak one geometry. In the vocabulary of coalgebraic logic the generators are Moss's cover modality  $\nabla$  applied to the basis (the presentation of the Vietoris powerlocale by generators and relations [233]); the internal one-sentence reading — the carrier is the Vietoris powerlocale of the compactified ambient object, constructed inside the sheaf topos, with the ray-ambient carrier its shadow along the anchored tower — is design at prose grade, recorded because it explains why the objectwise-then-glue construction is canonical (presentations by generators and relations pull back along inverse-image functors), while everything this chapter builds on is the external, objectwise, kernel-checked form above.

#### 9.4.4 What the Carrier Hands the Later Sections

Four interfaces, each consumed downstream with its receipt already in hand: (i) per window, a compact Hausdorff second-countable hyperspace with a crescent basis — the home of the class stratum; (ii) Fell-continuous restrictions, so preimages of locally closed classes are locally closed, and class-level structure transports contravariantly along the site for free; (iii) the descent homeomorphism, so any fibrewise construction commuting with clipping globalizes along covers with no further argument — the fibre sheaf of [section 9.8](#) consumes exactly this; (iv) the determination principle, so laws over records are determined by their evaluations on countably many rationally indexed observations — the exact-stratum face of the denotation stack.

### 9.5 The Universe of Beliefs

#### 9.5.1 Heights, Grades, and the Order

**From verdicts to heights.** In the behavioural reading, a System denotes a set of trajectories and a specification denotes a superset test: allowed or forbidden, no third value, no weighting, and no way for the model to confess that it may fail to produce a full trajectory at all. The present universe replaces the verdict object with heights. A System's denotation is a *belief* — in full, a *level-of-inconsistency functional* — on probability distributions over the record space: a lower semicontinuous function

$$\sigma: \Delta(\mathcal{X}) \longrightarrow [0, \infty],$$

whose value  $\sigma(\mu)$  is the level of inconsistency between the conceivable distribution  $\mu$  and what the object asserts —  $\sigma(\mu) = 0$ : fully consistent;  $\sigma(\mu) = \infty$ : excluded outright; intermediate heights price partial inconsistency [54, 209]. The functional is the belief; the distributions are what it scores — imprecision, nondeterminism, and graded confidence are all shapes of the belief, never features of a distribution. (The mechanized development carries its functionals on the subprobability carrier  $\Delta_{\leq 1}(\mathcal{X})$ ; the members of the universe are the *radial* ones — height determined by a law's direction alone — and on those the compile of [section 9.6](#) is exact: graded functionals on probability laws on one side, closed radial *sets* of subprobability laws on the other, the functional presentation for arithmetic and the body presentation for order. The partiality paragraph below says how a leaky process reads.) Membership in the universe is lower semicontinuity, *and nothing else*: convexity is not an admissibility condition, and the convex members form distinguished subclasses of the universe rather than the universe (Remark 9.20). Specs consume the same stock one storey up: a Spec's denotation is a constructible class of the bodies these beliefs compile to ([section 9.6](#) and [section 9.7](#)), so the beliefs of this section are the raw material of both sides of the eventual judgments, and of the composition calculus's fibre data.

A single coin toss already exhibits the range. Over the two-point record space  $\{\text{heads}, \text{tails}\}$ , three members of the universe: the belief vanishing at the fair law and infinite everywhere else (a precise model — the coin is fair, and nothing else is admitted); the indicator of the closed set  $\{\mu : \mu(\text{heads}) \leq \frac{1}{3}\}$  (a hard constraint, with no preference expressed inside it); and the relative-entropy belief  $\mu \mapsto \text{KL}(\mu \parallel \text{fair})$  (every

law admitted, priced by its divergence from fairness). The first two are the degenerate faces of Remark 9.22; the third is a smooth interior member; and the order below compares all three on one scale.

**The order.** The universe is ordered pointwise:  $\sigma \geq \varphi$  when  $\sigma(\mu) \geq \varphi(\mu)$  for every distribution  $\mu$  — the greater belief is the stronger assertion, at least as inconsistent with every distribution. Read as implication — the stronger belief implies the weaker — the pointwise order makes the universe a thin category of beliefs, with implications as its morphisms [54]. This pointwise order is the order of the universe at the present storey; on the radial stock, under the compile of section 9.6, it is exchanged, anti-monotonically, with *inclusion* of bodies, and inclusion is the form in which everything above this storey — classes, fibres, and the judgments of later chapters — consumes it. No satisfaction judgment is defined in this chapter; what the chapter fixes is the ordered universe those judgments will be read in.

*Remark 9.14* (Mechanization status of the universe stratum). The universe stratum is kernel-checked in three storeys, and the carrier is held pointfree first. *The pointfree storey*, at record-space generality with opens and covers first-class: the carrier is the space of valuations on the frame of opens — strict, monotone, modular into  $[0, \infty]$ , Scott continuity carried as a mixin exactly where a theorem consumes it (Pointfree.Valuation.Basic) — with the whole polarity package proved there: the promotion adjoining the cemetery outcome is a homeomorphism onto the induced topology, its mass-monotone half-spaces the cemetery coordinate’s lower half-spaces (promoteHomeomorph, induced\_promote\_eq); evaluations lower semicontinuous at opens, mass upper semicontinuous, liveness walls closed (Pointfree.Valuation.Topology); and escaping mass is witnessed without a single point — the free-ultrafilter valuation fails Scott continuity against a directed family of opens, and the Dirac net converges to it in the lower topology (Pointfree.Valuation.EscapeWitness). *The classical storey*, as the bridge: restricting a Borel measure to opens is a valuation, Scott-continuous exactly on the  $\tau$ -additive stratum — and on second-countable carriers every Borel measure is  $\tau$ -additive [83, 414O], so the measure-theoretic dialect of this chapter is a corollary of the pointfree one, the hypothesis class mechanized as stated (Pointfree.Valuation.Bridge). The classical subprobability carrier itself is kernel-checked at that generality:  $\Delta_{\leq 1}(\mathcal{X})$  as SubProbabilityMeasure under the narrow topology, its restriction map into the pointfree carrier continuous (SubProbabilityMeasure.continuous\_toSubProb), the promotion’s classical face the measure-level dagger chart  $\Delta_{\leq 1}(\mathcal{X}) \cong \Delta(\mathcal{X} \sqcup \{\dagger\})$ , a homeomorphism for the weak topologies (daggerChartMeasure), with the compactness dividend for compact carriers proved by two independent routes (compactSpace\_of\_daggerChartMeasure) and metrizability over metrizable separable Borel carriers (metrizableSpace\_subProbabilityMeasure, Pointfree.Measure.DaggerChart). Beliefs, the compile, and the closedness dictionary over this general carrier are the subject of Remark 9.18 (SuFunctor.Universe.General). *The finite storey*: the carrier  $\Delta_{\leq 1}(V)$  over a finite outcome type as SuFunctor.Universe.belCarrier/BelState (compact, convex — convex\_belCarrier, isCompact\_belCarrier), with the probability face as probCarrier/ProbState; beliefs on the subprobability carrier as Penalty — the mechanization’s name for the type of beliefs — with lower semicontinuity the standing membership hypothesis; the pointwise order itself, under the name the development gives its comparison relation (SuFunctor.Universe.Judgment: Sat, definitionally  $\varphi \leq \sigma$  — a name this chapter reads purely as the order); the order-level faces of the connectives (conjunction’s universal property sat\_sup\_iff; the functional-level disjunction minimum with its universal property entails\_inf\_iff and the hedging witness exists\_sat\_inf\_not\_sat — section 9.7 adjudicates which disjunction the logic’s  $\vee$  is); the closure package for the operations the calculus performs on members (SuFunctor.Universe.Closure: lower semicontinuity closed under addition, binary and countable suprema, and affine tilts); and two generation theorems that pin the universe to certificate-shaped data — rational threshold rows see the whole probability face (SuFunctor.Universe.Generation: iSup\_boxRows\_eq\_self, with countable index, stated for beliefs on the probability carrier), and over the compact finite-dimensional subprobability carrier quadratic gambles see the whole universe (SuFunctor.Universe.Tents: iSup\_tents\_eq\_self). The probability-face height data of the radial presentation below is mechanized separately as ProbPenalty. And the judgment tier itself is kernel-checked at the general carrier (SuFunctor.Universe.General: modules Faces, ClosureGeneral, GenerationGeneral): the order faces of the connectives — conjunction’s universal property, the functional-level minimum with its universal property, and the hedging witness, the last on every nonempty carrier (General.sat\_sup\_iff, General.entails\_inf\_iff, General.exists\_sat\_inf\_not\_sat) — together with wall citizenship (closed if and only if citizen, General.lowerSemicontinuous\_wall\_iff) and the wall algebra; the closure package over an arbitrary topological carrier — addition, binary and countable suprema, pullback, and tilts by bounded continuous nonnegative scores, the general

form of the finite storey's affine tilts; and generation by *gamble rows* — rational heights on finite menus of rational thresholds against bounded-continuous-gamble expectations, the certificate shape — as a directed supremum with no countability, metrizable, or compactness consumed anywhere (`General.isSup_gambleRows_eq_self`, through `isInducing_testProfile`: the carrier's topology is the initial topology of its gamble reads), and with countable index under second countability of the carrier, a hypothesis discharged for compact metrizable record spaces (`General.exists_countable_gambleRows_eq_self`, `General.secondCountableTopology_probabilityMeasure`); the quadratic-tent species stays finite-dimensional by nature — its general sibling is the gamble-row theorem. The record-space stratum —  $\mathcal{X}$  Polish, the standing structure below — is the semantic generality this chapter is written at, and the mechanization meets it at this storey; where a theorem below is kernel-checked at the finite stratum only, its remark says so.<sup>3</sup>

**Grades, and the two scales.** The multiplicative presentation of the same universe replaces heights by *grades*  $g = e^{-\sigma} \in [0, 1]$  (hard violation graded 0), under which addition of beliefs is multiplication of grades and the order reverses. Both scales are used below — heights compose additively under the wiring calculus, grades multiply, and the kernel-checked composition dictionary is deliberately stated through an abstract exponential so that no transcendental function enters the exact stratum. The grade scale is where a familiar family of models lives: for  $\sigma = \beta^{-1} \text{KL}(\cdot \| p)$  the penalized worst case is the Gibbs variational formula, and relative-entropy beliefs toward a reference — the inconsistency semantics of probabilistic dependency graphs of Richardson and Halpern [209] — sit in the universe as smooth interior members. The differentiator the universe adds is its boundary strata: credal flats (a set of laws held with no interior preference — nondeterminism is this imprecision, and no finite-temperature relative-entropy chart expresses a flat) and walls (the possibilistic face), which arise from the smooth chart only as its zero-temperature limit — though the *set-referenced* relative-entropy chart, the Hausdorff-KL embedding of Remark 9.20, expresses exactly a flat with relative-entropy grading off it: the intermediate stratum between the smooth interior chart and the walls.

**Partiality is first-class.** A belief is a functional on probability distributions; partiality enters through the *compile*, not through the domain. The body of a member (section 9.6) is a *radial* subset of the subprobability carrier  $\Delta_{\leq 1}(\mathcal{X})$  — it admits each law at every scale up to its grade, so admitted mass need not reach one — and at that storey the denotation is a set, no longer a functional. A leaky process — one that may halt, diverge, or exit scope — denotes along the same rays as its total counterpart, at the grade its surviving mass earns: *killing raises the level of inconsistency*, and the ray's grade axis is the only bookkeeping the leak requires. (The mechanized development also carries the promotion  $\Delta_{\leq 1}(\mathcal{X}) \cong \Delta(\mathcal{X} \sqcup \{\dagger\})$  as a kernel-checked chart — an affine homeomorphism, not a compactification — for the computations that want normalized mass; it is an available presentation, not a second axis of the universe.) The asymmetry the radial down-closure buys is the discipline the universe exists to enforce: leaked mass can only lower the probability of reaching a bad event, so safety certificates checked against full-mass semantics remain sound; what leak *lights* is liveness — lower bounds on good events feel every lost unit of mass — and a liveness claim cannot be laundered through a model that is allowed to quietly stop. The envelope apparatus below accounts for this exactly, and the kernel carries the counterexample that keeps the accounting exact (the leak-aware safe-side bound and its total-leak fixture, Remark 9.25).

**Connectives, composition, and the one inequality.** On denotations the logic's conjunction is the pointwise join,  $\sigma_1 \vee \sigma_2 = \max(\sigma_1, \sigma_2)$  — the least demand at least as strong as both — and lower semicontinuity is closed under it. Composition of *Systems*, by contrast, is addition: the wiring calculus of section 9.9 composes belief content by pushforward-then-add — a composite holding several beliefs at once asserts their sum, the overall belief being the sum of its parts [54] — and addition is not idempotent. The whole relationship between the two monoids is one inequality with an exact error term:

$$\max(\sigma_1, \sigma_2) \leq \sigma_1 + \sigma_2 = \max(\sigma_1, \sigma_2) + \min(\sigma_1, \sigma_2),$$

<sup>3</sup>One vocabulary caution: this finite storey is the composition ladder's *finite* stratum — finite outcome carrier. The ladder's *exact* stratum is a different rung: finitely supported joints over an arbitrary carrier, with arbitrary real weights. Over a finite outcome type the rungs collapse — the seam embedding is a bijection, so the finite storey, the exact stratum, and the general carrier present one object (`toMeas_surjective`); over infinite carriers they are genuinely nested, and Remark 9.33 settles which claims complete across each step, and which provably do not.

pointwise. Composition dominates conjunction — the sound direction: a bound certified against the join holds a fortiori against the composite — and the two agree at a distribution precisely when the beliefs are *crisp* there: the lesser zero, or the greater infinite. (In the extended nonnegative reals the identity’s min-term is not a cancellative error one may subtract: at a distribution where the two values are  $\infty$  and 1 the sum and the join agree by absorption while the lesser value is 1.) The *crisp locus* — crisp at every distribution — is exactly the agreement locus, and that is why deterministic intuition reads the two operations as one: on walls they agree, everywhere. (That no wall-fragment verdict can even observe the gap off the crisp locus is a two-line fact displayed in [section 9.12](#), where the wall fragment lives.) The gap itself is quantified conservatism in the safe direction, never unsoundness — the slice bracket  $\{\max \leq s/2\} \subseteq \{\text{sum} \leq s\} \subseteq \{\max \leq s\}$  for two contributors. The inequality and its sublevel bracket are kernel-checked at the finite-rational stratum and space-free (`QtslAux.Imprecise.MarginalCompat: sum_dominates_sup, sublevel_marginal_of_dominates`; the general form over arbitrary joint models in `QtslAux.Imprecise.MarginalCompatGeneral`). Disjunction is deliberately absent from this paragraph: at the functional level the pointwise *minimum* is the lattice join of demands and is sound for the single-conclusion fragment, but the class stratum of [section 9.7](#) shows that the specification logic’s disjunction must be read one level up, as plain union of classes, and that anything else — the minimum included, against class-valued conclusions — fails disjunction elimination. The connective’s true home is there.

### 9.5.2 The Standing Structure, and the Radial Compile

The record spaces everything above quantifies over are fixed once, and the next definitions carry the credal presentation of the universe’s members. The compile below ([Definition 9.17](#)) is an isomorphism: lower semicontinuous beliefs on *probability* distributions correspond exactly to closed *radial* subsets of the subprobability carrier — sets containing, with each law, its whole ray  $\{\gamma\mu : 0 \leq \gamma \leq 1\}$  down to the zero measure — with no residue on either side (kernel-checked at the general carrier, `SuFunctor.Universe.RadialUniverse: compileEquiv`). The two presentations are two charts on one universe, and each computation uses whichever is natural: algebra of beliefs — sums, divergence pricing, affine tilts — happens on the probability-face chart, where the operations are pointwise; order, gluing, and the classes happen on the body chart, where the order is inclusion. The grade dictionary  $g_S = e^{-f}$  carries one chart to the other.

The presentation meets the order as walls: a credal body  $S$  enters the order as its indicator  $\chi_S$ , under which domination is containment of finiteness sets — the wall reading of [section 9.12](#) — and the denotation’s own geometry is carried by the *body*  $S$  itself, which is what the classes of [section 9.7](#) quantify over. A compiled *law* enters as its ray — the body of the precise belief in that law — and every wall’s body contains the zero measure, because every body does: bottom-inclusion is a theorem of radiality, not a convention (`rwall_ne_top`: no wall built on the radial entry can exclude the empty process). The consequence is load-bearing for composition. Asserting  $x = y$  of a process claims only that no live behaviour violates it; the conjunction of jointly unsatisfiable constraints —  $x = y$ ,  $x = 0$ ,  $y = 1$  — denotes the *bottom body*  $\{0\}$ , the lawful belief that no live behaviour exists at all, never an ill-formed exclusion of the inconsistent world itself (kernel-checked as stated, with that three-clause example: `contradictory_composite_denotes_bot`). A construct that vanished only at one pinned nonzero law — an “equality floor” claiming the whole universe consistent — is not a member of the universe at all: no belief compiles to a pinned point (`compile_ne_singleton`), and feasibility is therefore never smuggled through an equality; it is asserted, when it is asserted, by the explicit liveness face of the presented classes ([section 9.7](#)).

Every System this book compiles denotes through the mechanism-and-gluing stack below: a credal body for the precise and glued stochastic faces, and, for adversary-quantified faces, the closed *convex hull* of the admitted family’s union (the hull-vs-union adjudication is [Remark 9.23](#)’s). An empty admitted family denotes the bottom body along with every other unsatisfiable composite; no compiled System falls outside the body calculus. The classical imprecise-probability apparatus lives on the same stock, and everything below is stated there.

**Definition 9.15** (Standing structure; credal bodies). *Standing structure.* Throughout the denotation stack, the *record space*  $\mathcal{X}$  is a *Polish space* — a separable, completely metrizable topological space — carrying its Borel  $\sigma$ -algebra. Polishness here is a theorem about the toolkit’s spaces, not a further dial: the handy widgets are all objects of the completed state-space category of [section 9.2](#) — countable families of  $\omega$ -semialgebraic sectors, where local closedness, the membership condition of that section, already implies  $G_\delta$  sector by sector, hence Polish (a countable disjoint union of Polish spaces is Polish) — except record spaces, which

are handled through their own mechanism involving the spacetime site and the Fell topology, and arrive Polish by their own route. In particular:

- finite sets are the dimension-zero  $\omega$ -semialgebraic spaces (discrete topology):  $\Delta(\mathcal{X})$  is the probability simplex in  $\mathbb{R}^{\mathcal{X}}$ , whose rational points are the exactly-representable distributions;
- semialgebraic sets carry the subspace topology from  $\mathbb{R}^n$ , and the locally closed  $\omega$ -semialgebraic sets of [section 9.2](#) — the carrier class of this book’s exact certificates, closed under finite disjoint union, containing the finite sets as dimension-zero instances, with the cemetery compactification applied at the carrier tier as in [section 9.2](#) — are the standing state-space class;<sup>4</sup>
- bag spaces with pieces in a common ambient are  $\omega$ -semialgebraic natively: a countable disjoint union of locally closed semialgebraic pieces of one ambient dimension is the class’s own bag pattern, every summand clopen in the union (its cemetery is the carrier-tier operation, as always — the bag’s local compactness is all the operation needs); the quotient of a semialgebraic set by a linear action of a finite group is again semialgebraic (embed by a generating family of polynomial invariants; the image is semialgebraic by Tarski–Seidenberg), which covers each symmetric power  $\text{Sym}^n(X) := X^n/S_n$  individually. The full bag space  $\coprod_{n \in \mathbb{N}} \text{Sym}^n(X)$  has unbounded ambient dimension across its summands — which no common-ambient tagged union can host — and it is a *first-class object* of the completed state-space category: a countable family of sectors, each symmetric power its own sorted-cone carving (one basic rational piece, `sortedCone`, `mem_sortedCone_iff_monotone`), the space literally the coproduct of its sectors (`bagObj`, `bagIsColimit`, `SuFunctor.StateSpace.FamCompletion`), Polish since every sector is (each clopen in the union). At the Borel stratum this is the bag monad of Dash and Staton [58], and the Bag former of [chapter 12](#) is its System-level lift;
- manifold-flavoured state spaces (Lie groups, Riemannian configuration spaces) enter through their polynomial-data presentations: in this book’s practice they are carved by polynomial data, and every compact smooth manifold is diffeomorphic to a real algebraic set (Nash–Tognoli), so the class loses nothing a certificate could have consumed; all manifolds in this book are second countable;
- record spaces are the exception, handled through the spacetime site and the Fell topology rather than by carving: per window the record carrier of [section 9.4](#) is a compact metrizable hyperspace — Polish outright — with laws pinned by the countable rational determination of [Theorem 9.12](#); for record spaces presented by gluing along finite windows, countable products and countable limits of Polish spaces are Polish, and the cylinder  $\sigma$ -algebra generated by the finite-window restriction maps coincides, in the standard presentations, with the Borel structure of the product realization.

$\Delta(\mathcal{X})$  denotes the set of (countably additive) Borel probability measures on  $\mathcal{X}$ , and  $\Delta_{\leq 1}(\mathcal{X})$  the set of *subprobability* measures (total mass at most 1). Both carry the *weak* (narrow) topology; for Polish  $\mathcal{X}$  this topology on  $\Delta_{\leq 1}(\mathcal{X})$  is metrizable, and for finite  $\mathcal{X}$  it is the Euclidean topology on the subprobability polytope, which is compact. All occurrences of “topologically closed” and “lower semicontinuous” in this stack refer to this topology. The total mass  $\|\nu\| := \nu(\mathcal{X})$  is weakly continuous — and that continuity is why the weak topology, rather than its locally compact cousin, is the topology of record: under the *vague* topology (tests vanishing at infinity, on a locally compact carrier) the subprobability space would be compact at the price of letting mass leak silently in limits —  $\delta_n \rightarrow 0$  vaguely on  $\mathbb{N}$  — which is exactly what liveness constraints cannot survive: for every  $p > 0$  the set  $\{\nu : \|\nu\| \geq p\}$  is weakly closed because mass is weakly continuous, and is not vaguely closed. And the choice is forced, not preferred, by the promotion itself — mechanized pointfree, at record-space generality, with opens and half-spaces first-class (module `Pointfree.Valuation.Topology`): along the promotion that adjoins the cemetery outcome the narrow topology is exactly the induced topology, its mass-monotone half-spaces the cemetery coordinate’s lower half-spaces (`induced_promote_eq`, the promotion a homeomorphism, `promoteHomeomorph`), so the stack’s polarity holds by construction — evaluations lower semicontinuous, mass upper semicontinuous, liveness walls closed (`lowerSemicontinuous_eval`, `upperSemicontinuous_mass`, `isClosed_liveness_wall`) — and the Borel reading enters afterwards, as a bridge rather than a foundation: on second-countable carriers every Borel measure is  $\tau$ -additive [83, 414O], which is what lets the measure-theoretic dialect of this section stand as a corollary of the topological one. Partiality therefore enters this universe explicitly, as the cemetery outcome of the promotion above, never implicitly as a topological limit. Every  $\nu \in \Delta_{\leq 1}(\mathcal{X})$

<sup>4</sup>A subspace of  $\mathbb{R}^n$  is Polish if and only if it is  $G_\delta$  (Alexandrov). A locally closed set is the intersection of an open and a closed set, hence  $G_\delta$  — and, being locally compact and second countable, Polish twice over; per-sector local closedness is the certificate, and the disjoint union inherits both properties with every summand clopen.

with  $\nu \neq 0$  has a unique *ray decomposition*  $\nu = \gamma\mu$  with  $\gamma = \|\nu\| \in (0, 1]$  and  $\mu = \nu/\|\nu\| \in \Delta(\mathcal{X})$ ; the zero measure is the bottom element, written  $0$  or  $\perp$ .

*The object.* A *credal body* on  $\mathcal{X}$  is a subset  $S \subseteq \Delta_{\leq 1}(\mathcal{X})$  such that

(C1)  $0 \in S$ ;

(C2)  $S$  is topologically closed;

(C3)  $S$  is *radial* (downward-scaling-closed):  $\nu \in S$  and  $\lambda \in [0, 1]$  imply  $\lambda\nu \in S$ .

(Given (C3), axiom (C1) says exactly that  $S$  is nonempty.) Convexity is deliberately not a condition: closedness is the whole of the regularity demanded, and it is exactly the body-side face of lower semicontinuity, through the correspondence below. The convex credal bodies are a distinguished subclass, catalogued with their relatives in Remark 9.20.

*Grade and radial structure.* For  $\mu \in \Delta(\mathcal{X})$  the *grade* of  $\mu$  in  $S$  is  $g_S(\mu) := \max\{\gamma \in [0, 1] : \gamma\mu \in S\}$ , the largest admitted scaling of  $\mu$ ; the maximum is attained, because  $\{\gamma : \gamma\mu \in S\}$  is a closed subset of  $[0, 1]$  containing  $0$ . By (C3) the intersection of  $S$  with the ray through  $\mu$  is exactly the closed segment  $[0, g_S(\mu)] \cdot \mu$ : a credal body is determined by its grade function.

*The radially maximal slice.* The *radially maximal slice* of  $S$  is the set of its measures of maximal admitted scale:

$$S^{\max} := \{\nu \in S : \lambda\nu \notin S \text{ for every } \lambda > 1\} = \{g_S(\mu)\mu : \mu \in \Delta(\mathcal{X}), g_S(\mu) > 0\}.$$

The zero measure is never radially maximal, so  $S^{\max} = \emptyset$  if and only if  $S = \{0\}$ , the *bottom credal body*.

*Remark 9.16* (Why the lower envelope reads the maximal slice). Axioms (C1) and (C3) are not optional conveniences: they are what makes the belief correspondence below exact, and the bottom credal body  $\{0\}$  the lawful denotation of infeasibility — the empty set is not a credal body at all, and nothing in this universe ever denotes it. But the axioms force  $0 \in S$ , so for any nonnegative gamble  $h$  the naive infimum over all of  $S$  is degenerate:  $\inf_{\nu \in S} \int h d\nu = 0$  identically, attained at  $\perp$ . The operative lower envelope therefore reads the radially maximal slice, and the upper envelope is unaffected on the gambles that matter: for  $h \geq 0$  and  $S \neq \{0\}$ ,  $\sup_{\nu \in S} \int h d\nu = \sup_{\nu \in S^{\max}} \int h d\nu$ , since every nonzero admitted measure is dominated along its ray by its slice representative. (For gambles taking negative values the supremum must be taken over all of  $S$ .) Degenerate case, with the two sets kept straight: at bottom the *body* is the nonempty set  $\{0\}$  while the *slice* is empty, so with  $\inf \emptyset = +\infty$  the lower prevision of every gamble degenerates to  $+\infty$  while the upper prevision is  $0$ . *Ex falso quodlibet* is the wrong lesson here: the bottom body is not a contradiction from which every verdict follows but a lawful denotation with a definite, one-sided verdict profile. The upper envelope reads the whole body at bottom as everywhere else, and at  $\{0\}$  it reports the zero measure's own values: every event has upper probability  $0$ , so every safety-shaped verdict — an event upper bound, a down-closed constraint — is satisfied at bottom, at the zero measure rather than vacuously; equivalently, since the axioms force  $0 \in S$  for every credal body,  $\{0\}$  is the least body and lies inside every safety face's body. The lower envelope's  $+\infty$ , by contrast, is the arithmetic of an empty index set, not a verdict: a liveness-shaped judgment carries an existential commitment — the class stratum below writes it as an escape clause,  $K \cap S(v)^c \neq \emptyset$  — that the bottom body can never witness, because the zero measure never leaves any demand's body. Reading the vacuous  $+\infty$  as satisfaction of every positive lower threshold would decide those judgments in the wrong direction. The mechanized verdict split of Remark 9.23 enforces the discipline: the slice-reading recovery theorems carry the  $\mu \neq 0$  fence (`satCredal_lower_rayC_geC`), the bottom body is the unique credal set with empty slice (`maxSlice_rayC_empty_iff`), and the ray's zero element is the universal refuter of every positive threshold read over the whole set (`not_satCredal_upper_rayC_geC`). The verdict profile of infeasibility is therefore *all safety, no liveness*: an infeasible denotation satisfies every safety constraint and witnesses no liveness demand — the sound behaviour for the denotation of infeasibility — and the presented class stratum builds the profile in structurally: every presented atom's liveness family carries the properness demand, so the infeasible system belongs to no presented atom's class (`top_notMem_modelClass`; Remark 9.31), the refusal located in the liveness conjunct alone while the safety containment holds throughout.

**Definition 9.17** (Beliefs on the probability face; the radial compile). Adopt the standing structure of Definition 9.15, together with the arithmetic conventions  $e^{-\infty} := 0$  and  $-\log 0 := +\infty$ . The *radial compile* of a belief  $f: \Delta(\mathcal{X}) \rightarrow [0, \infty]$  is

$$S(f) := \{\gamma\mu \mid \mu \in \Delta(\mathcal{X}), \gamma \in [0, e^{-f(\mu)}]\} \subseteq \Delta_{\leq 1}(\mathcal{X}),$$

and the *belief of* a credal body  $S$  is  $f_S(\mu) := -\log g_S(\mu)$ . The two directions are mutually inverse bijections between the lower semicontinuous beliefs on  $\Delta(\mathcal{X})$  and the credal bodies on  $\mathcal{X}$  — lower semicontinuity on the belief side corresponds exactly to closedness on the body side, with no further condition on either — under which the grade dictionary reads  $g_{S(f)} = e^{-f}$ , and inclusion of credal bodies corresponds anti-monotonically to the pointwise order on beliefs:  $S(f) \subseteq S(h)$  iff  $f \geq h$ . The everywhere-infinite belief compiles to the bottom credal body  $S(\infty) = \{0\}$  — never to the empty set — so infeasibility (the sum of two contradictory beliefs, say) denotes a lawful credal body and the correspondence has no excluded cases.

*Remark 9.18* (Mechanization status of the compile correspondence). Kernel-checked at the *general* carrier — subprobability Borel measures over an arbitrary topological measurable record space, under the narrow topology,  $[\text{Nonempty } \mathcal{X}]$  the one standing hypothesis (the bottom body  $\{0\}$  needs a direction to point at) — in `SuFunctor.Universe.General`: closedness of the compile is *equivalent* to lower semicontinuity of the belief, both directions (`isClosed_compile_iff`), and the image characterization closes the bijection there — every nonempty closed radial set is the compile of exactly one lower semicontinuous belief (`exists_lsc_compile_eq_iff`), the ray gauge attained ray by ray (rays are compact for *any* carrier), its belief reconstructing the body (`compile_rayPenalty`), the compile injective (`compile_injective`), the reconstruction law `rayPenalty_compile` now unconditional — an upgrade over the finite-stratum form, which consumed a citizenship hypothesis — and upper semicontinuity of the gauge (`upperSemicontinuous_rayGauge`) the grade-side face of closedness. The proof shape is the pointfree one, which is why no metrizable, no sequences, and no  $\liminf$  bookkeeping appear anywhere: mass is the narrowly continuous observation, direction is continuous wherever mass is bounded away from zero, and the grade side carries the left-limit content algebraically (`le_gradeN_of_forall_lt`) — the topological leg of the correspondence is a theorem *past* the Polish form, not a Polish-stratum concession. The finite stratum remains kernel-checked as the exact reference case (`SuFunctor.Universe.compile`, `SuFunctor.Universe.VietorisStratum`, `SuFunctor.Universe.ImageChar`), and the convex substratum carries a second, exact-rational and exponential-free mechanization (`QtslAux.Imprecise.PenaltyCredalIso`, in the multiplicative grade coordinates  $g = e^{-f}$ : exponential-convexity of the belief corresponds exactly to convexity of the body — the harmonic-mean inequality in cross-multiplied form — the ray-segment description carries attainment of the grade as data, and radially there a theorem, mixing with the zero measure being downward scaling: one place where convexity genuinely pays). The grade dictionary for the composition law — the grade of an additive composite is the *product* of the grades, through any abstract exponential — is proved in the same module. The mechanizations agree on their shared strata through the seam isomorphism of Remark 9.48.

**Example 9.19** (Conditional beliefs, independence beliefs, and what composition does not assume). Two epistemic states arise so often in modelling practice that their compiles are worth stating once, on a record space that factors,  $\mathcal{X} = A \times B$ , with  $X$  and  $Y$  the coordinate observables of a joint law  $\mu \in \Delta(\mathcal{X})$ . Neither is a probability distribution about anything: each is a condition *about* joint laws — exactly the shape of epistemic content that forces the belief reading in the first place [54].

*Conditional beliefs.* The belief “ $X$  given  $Y$  has conditional law  $k$ ” —  $k$  a probability kernel from  $B$  to  $A$  — compiles, crisply, to the set of joints whose disintegration along  $Y$  agrees with  $k$  at  $\mu_Y$ -almost every  $y$ : inconsistency 0 there,  $+\infty$  elsewhere, the body the radial closure of that set. Richardson’s weakening [209] grades the wall instead of asserting it: with a confidence weight  $\beta > 0$ , the belief is the scaled conditional relative entropy

$$f(\mu) = \beta \int_B \text{KL}(\mu(\cdot | y) \| k(\cdot | y)) d\mu_Y(y) = \beta \text{KL}(\mu \| \mu_Y \times k),$$

where  $\mu_Y \times k$  is the joint with  $Y$ -marginal  $\mu_Y$  and conditional  $k$ : each conceivable joint is charged the divergence of its *actual* conditional from the believed one, at a rate set by the confidence. Since  $\mu \mapsto \mu_Y \times k$  is affine and  $\text{KL}$  is jointly convex and lower semicontinuous, these beliefs are convex and *lsc* — they are the per-edge terms of the probabilistic-dependency-graph inconsistency measure, the family whose classical verification the Richardson chart of Remark 9.20 records — and the crisp wall is their  $\beta \rightarrow \infty$  limit. (Kernel-checked at the finite stratum, `SuFunctor.Universe.EpistemicStates`: affinity is `condTarget_mix` — proved, not assumed — joint convexity of the divergence is `klq_mix_mix_le`, lower semicontinuity `lowerSemicontinuous_condPenalty`, and the zero set is the agreement of the disintegration with  $k$  at every  $y$  of positive mass, `klq_condTarget_eq_zero_iff` — the almost-everywhere guard is load-bearing in exactly that disintegration-ratio form, while the equivalent joint-coordinate form absorbs it.)

Figure 9.2: The atlas of credal-body subclasses (Remark 9.20) as a Hasse diagram, higher = larger. Every edge is a strict inclusion — placement a general-carrier theorem, strictness a two-point rational witness — and every pair not joined by a path is incomparable, both directions witnessed over the same two-point outcome space; the receipts are the modules cited in the remark. The credal-set class enters by radial embedding, and precise models are its singleton corner.

*Independence beliefs.* The belief “ $X$  and  $Y$  are independent” is, in graded form, the functional proportional to the *mutual information*,

$$f(\mu) = \beta I_\mu(X; Y) = \beta \text{KL}(\mu \parallel \mu_X \otimes \mu_Y),$$

zero exactly on the product laws, so the crisp face has body the radial closure of the product laws. The belief is lsc — KL is jointly lsc and marginal-product formation is weakly continuous; on finite record spaces  $I_\mu$  is continuous outright — but *nothing here is convex*: a mixture of two product laws is not a product law (mixing  $\delta_{(0,0)}$  with  $\delta_{(1,1)}$  in equal parts manufactures perfect correlation from two deterministic independencies), so the crisp independence body is closed, radial, and non-convex, and  $I_\mu$  is neither convex nor concave in the joint. Independence beliefs are the ordinary inhabitant of  $\mathbf{CB} \setminus \mathbf{CV}$  in the atlas below: the universe’s stock demands closedness and radially but not convexity because one of the most common beliefs in the modelling vocabulary would otherwise not denote. (Kernel-checked, same module: zero-iff-product is `mutualInfoQ_eq_zero_iff`, continuity outright `continuous_mutualInfoQ`, the two-delta witness `Witness.not_penaltyConvex_indepPenalty`, and the membership itself `indepBody_credalBody_not_convex` — stated in the atlas modules’ own credal-body vocabulary.)

*What composition does not assume.* Conjunction of beliefs is addition (the grade product, in the multiplicative chart), and a belief that reads only its own subsystem’s marginal constrains only that marginal. So when two Systems sit side by side with no wiring between them, the composite body is the set of *every* joint whose marginals lie in the two bodies — the whole Fréchet class of couplings — and not the independent coupling: absent an explicit causal dependency, the universe does not assume independent noise, because sums of marginal-reading beliefs cannot manufacture a correlation constraint. Independence is itself a belief, asserted when it is asserted — gradedly by the mutual-information belief above, crisply by its wall — and the default composite prices every coupling the marginals admit, which is the sound direction for certification: a verdict that survives the Fréchet class survives whatever the unmodelled world correlates. (Kernel-checked, same module: the composite body is the Fréchet class, `compile_marginalWallSum` with `marginalSum_eq_zero_iff`, and the correlated coupling of two uniform marginals witnesses that the composite never implies independence, `Witness.frechet_does_not_imply_independence`.)

### 9.5.3 The Atlas of Credal-Body Subclasses

*Remark 9.20* (The atlas of credal-body subclasses). The literature’s imprecise-probability objects sit inside the credal bodies as distinguished subclasses, and the inclusions between them are part of this universe’s content — Figure 9.2 draws the poset. Read through the compile, the same atlas is the chart of full subcategories of the thin category of beliefs drawn in [54], with the explicit transforms mechanized

here. The inclusion spine is kernel-checked at the *general* carrier — subprobability measures over an arbitrary record space, each placement below a theorem (`SuFunctor.Universe.General.CredalPoset`, `SuFunctor.Universe.General.Richardson`) — while the finite-rational stratum remains the reference case for the *separations*: every strict edge and every incomparability a two-line rational witness over a two-point outcome space, and the outer class containing all of them (`SuFunctor.Universe.CredalPoset.house_includes_all`). Two closure notions must be kept apart first: *radiality* ((C3): closed under scaling  $\nu \mapsto \lambda\nu$ ,  $\lambda \in [0, 1]$ ) and *down-closure* in the pointwise order on measures ( $\nu' \leq \nu$  setwise implies membership). Down-closure implies radiality; the converse fails — a single ray  $[0, 1] \cdot \mu$  is radial and, for non-degenerate  $\mu$ , not down-closed. With that distinction in hand:

- *precise models*: the rays  $[0, 1] \cdot \mu$  — closed, radial, convex; the compiles of the beliefs vanishing at a single law (Remark 9.22);
- *credal sets*, in the sense of Cozman’s credal-network literature [50]: nonempty closed convex sets  $M$  of *full-mass* laws, entering as the radial closure  $[0, 1] \cdot M$ , with  $S^{\max} = M$  — and closedness of the radial closure is proved *through the dictionary*: the radial embedding of a closed convex full-mass set is the compile of its direction wall (`scaleSegment_eq_compile_dirWall`), so the body-side regularity is Remark 9.18’s closedness theorem applied, not a separate argument. A credal set enters the universe twice over: as its *wall* — the indicator belief  $\chi_M$  of Remark 9.22, the possibilistic reading — and as its *Hausdorff-KL embedding*  $\mu \mapsto \min_{\nu \in M} \text{KL}(\mu \parallel \nu)$ , the graded reading of the same set: zero exactly on  $M$ , relative-entropy-graded off it — the set-valued extension of the Gibbs chart of the grades paragraph above, with the direction of the divergence *forced* rather than chosen: under the epistemology’s multiplicative-weight update [54] (add the expected surprisal  $E_\mu(-\log L)$ , renormalize), the wall reading can only delete states, the reversed-divergence reading collapses to the vacuous belief, while the Hausdorff-KL reading conditions each member and charges it the surprisal of its own marginal likelihood — likelihood updating of weighted sets of probabilities in the sense of Halpern and Leung [108], whose zero set is the maximum-likelihood update of Gilboa and Schmeidler [92] (Dempster conditioning, on belief-function credal sets), and whose graded part retains exactly the marginal-likelihood record that element-wise conditioning [50] forgets (kernel-checked at the finite stratum, including the failure of the element-wise square: `SuFunctor.Universe.HausdorffKL`);
- *Richardson’s universe* [209]: bodies compiled from beliefs both *convex* and *lower semicontinuous* — with the provenance stated carefully, because the class is this universe’s reading of the programme, not a definition of Richardson’s: the probabilistic-dependency-graph programme never axiomatizes a codomain class at all — it proves convexity of its inconsistency measure as a lemma and never mentions semicontinuity — so the reading takes both properties as definitional, assuming them of the programme’s beliefs. The assumption is verified where checkable: the per-edge conditional relative entropies and their nonnegative combinations (the inconsistency measure itself) are jointly convex and lower semicontinuous, classically; the full  $\gamma$ -weighted scores, which add signed conditional-entropy terms, are convex exactly in the programme’s own weight regime (edge confidence at least  $\gamma$  times the structural weight — the programme’s convexity analysis states this bound, and outside it a two-outcome double-edge graph gives an exact rational counterexample). Neither half of the reading is redundant. Convexity of the belief is sufficient, not necessary, for convexity of the body —  $e^f$  convex is the exact condition, and on a two-point record space the belief  $\log(2 - \mu\{a\})$  is strictly concave along the simplex while its exponential is affine, a kernel-checked witness with its exact rational comparison (`QtstAux.Imprecise.PenaltyCredalIso`). And the lsc half is not implied by the convex half: a bounded, two-valued convex belief’s body can fail to be topologically closed, the failure a jump at the simplex boundary — a convex function is automatically continuous on the relative interior, so boundary-lsc is exactly what convexity leaves unsecured (`exists_penaltyConvex_not_closed`), and the same witness compiles to a body that no convex lsc belief compiles, so the two-property class is strictly smaller than the convexity-only reading would have been (`exists_penaltyConvex_compile_not_richardson`). The lsc half is thereby the half that makes the class a subclass of the credal bodies at all; the convex half is what places it under the convex bodies. The placement is a general-carrier theorem, exponential-free: additive convexity of the belief implies the exact grade-convexity criterion by weighted arithmetic-geometric means (`IsRichardsonBody.isConvexCredalBody`);
- the *convex credal bodies*: exactly the compiles of beliefs with  $e^f$  convex — at the general carrier the criterion is carried division-free, as the cross-multiplied harmonic form (`GradeConvex`), with the compile of any grade-convex belief a convex body (`convexBody_compile_of_gradeConvex`) —

and the subclass on which single-shot linear tests — prevision-shaped functionals, in the sense of Goubault-Larrecq’s prevision domains [96, 98] — are a complete instrument, by Fenchel–Moreau duality;

- *homogeneous ultracontributions* (Kosoy and Appel [143]): nonempty topologically closed *down-closed* convex sets of subprobability laws — inside the convex bodies, since down-closure implies radiality (`IsUltra.isConvexCredalBody`, at the general carrier). Every prevision-shaped body — a set cut out by a family of one-sided gamble constraints, the hyperspace object of Goubault-Larrecq’s superlinear-prevision domains — is an ultracontribution at the general carrier (`IsPrevisionBody.isUltra`); on the finite stratum the inclusion is an *equality* (`isPrevisionBody_iff_isUltra`): one poset node, two presentations, infra-Bayesian induction and the domain-theoretic prevision school meeting in one theorem — with the general converse Hahn–Banach-shaped, a named successor rather than a silent assumption;
- the  $C^\downarrow$  *monad* of Mio, Sarkis, and Vignudelli [182]: nonempty *finitely generated* down-closed convex sets — inside the ultracontributions wherever the setwise order of measures is narrowly closed, a hypothesis the mechanization carries explicitly rather than silently: hulls of finite generating families are compact for *any* carrier (the weight-simplex route), so finite generation implies closedness under exactly that named order-closedness (`isClosed_ptwiseDownHull`, `IsMVS.isUltra`) — free at the finite stratum, dischargeable on metrizable carriers, and not free in general;
- the semantics of Halpern and Leung’s minimax weighted expected regret [108]: topologically closed down-closed convex sets of subprobability laws *each containing at least one full-mass law* — the ultracontributions whose maximal slice reaches the probability face, which is condition-for-condition Kosoy and Appel’s *homogeneous ultradistribution* — although neither cites the other — the subprobability encoding being Halpern and Leung’s own.

Every class above is a class of credal bodies, so the present universe includes them all; the chain  $C^\downarrow \subseteq$  ultracontributions  $\subseteq$  convex bodies  $\subseteq$  credal bodies is strict at every step already over a two-point outcome space; the credal-set and precise classes enter through radial closure rather than down-closure (their radial closures are not down-closed in general); and the regularity that closes the whole atlas at the top is closedness alone — the lsc face of the compile, with no convexity anywhere in the outer class.

#### 9.5.4 Envelopes: Previsions and the Degenerate Faces

From either presentation the operators of record are the envelope expectations, split across the slice exactly as Remark 9.16 forces.

**Definition 9.21** (Lower and upper previsions of a credal body). Adopt the standing structure of Definition 9.15. A *gamble* is a Borel function  $h: \mathcal{X} \rightarrow (-\infty, +\infty]$  bounded below; its expectation under  $\nu \in \Delta_{\leq 1}(\mathcal{X})$  is well-defined in  $(-\infty, +\infty]$ . For a credal body  $S$  with radially maximal slice  $S^{\max}$ , the *lower prevision* and *upper prevision* of  $h$  under  $S$  are

$$\underline{E}(h) := \inf_{\nu \in S^{\max}} E_\nu(h), \quad \overline{E}(h) := \sup_{\nu \in S} E_\nu(h),$$

with  $\inf \emptyset = +\infty$  (so the bottom credal body — the nonempty set  $\{0\}$ , whose maximal slice is empty — has vacuously infinite lower previsions). For events we write  $\underline{P}(A) := \underline{E}(1_A)$  and  $\overline{P}(A) := \overline{E}(1_A)$ . The lower prevision must read the maximal slice (Remark 9.16); the upper prevision is defined over all of  $S$ , and for nonnegative gambles and  $S \neq \{0\}$  the suprema over the two index sets agree (the sets themselves do not). Full boundedness is required exactly where the two envelopes are *combined* — imprecision gaps and the attitude blends below — since those expressions are undefined when an envelope is infinite.

A specification’s probability operator  $P_{\geq p}[\varphi]$  denotes the lower probability  $\underline{P}(\varphi) \geq p$  — certification pessimism, always. Three faces of one object, and the flat operator survives as a face rather than a casualty:

*Remark 9.22* (The degenerate faces, stated exactly). The two flat verdict operators survive inside the credal stack as compiles of indicator-type beliefs.

1. *Precise face.* For  $\mu_0 \in \Delta(\mathcal{X})$ , the belief vanishing at  $\mu_0$  and infinite elsewhere is lower semicontinuous, and its compile is the single ray  $S = [0, 1] \cdot \mu_0$  with  $S^{\max} = \{\mu_0\}$ . The maximal slice is the singleton: both envelope operators then read  $\mu_0$  alone, and the denotation is an ordinary (precise) probability model. It is the slice, not  $S$  itself, that is a singleton — a credal body is never a one-point set except at bottom.
2. *Possibilistic face.* Let  $B \subseteq \mathcal{X}$  be a closed set of allowed records and  $D_B := \{\mu \in \Delta(\mathcal{X}) : \mu(B) = 1\}$  the distributions supported on  $B$  — convex, weakly closed, the closed convex hull of the point masses on  $B$ . The possibilistic belief (0 on  $D_B$ ,  $\infty$  elsewhere) is convex lower semicontinuous, and on this face upper probabilities are Boolean:  $\bar{P}(A) = 1$  if  $A \cap B \neq \emptyset$  and 0 otherwise, so  $\bar{P}(\text{bad}) = 0$  is the behavioural verdict “bad is forbidden.” The zero-set is all of  $D_B$ , not merely the point masses — with convexity no longer a membership condition, the point-masses-only belief is also a lawful member, whose body is the union of the rays through the point masses; when  $B$  contains at least two points that body is nonconvex and the belief sits strictly above  $\chi_{D_B}$  in the order (for empty or singleton  $B$  the two coincide), and the face that reproduces classical possibility theory is  $D_B$ .

The classical imprecise-probability world embeds by the same device one level up: an ordinary credal set  $M \subseteq \Delta(\mathcal{X})$  (nonempty, convex, closed, all elements of full mass) corresponds to the indicator belief  $\chi_M$ , whose compile is the radial closure of  $M$  with  $S^{\max} = M$  — the atlas of Remark 9.20 places this and its relatives. Strictly graded beliefs — the soft, dependency-graph-typed models — are exactly the credal bodies whose maximal slices contain submass measures.

*Remark 9.23* (The envelope calculus: the ray and its maximal slice). A precise law  $\mu$  denotes as its ray  $[0, 1] \cdot \mu$  — the credal body, its entry into the universe — and the wiring stratum computes with the ray’s *radially maximal slice*, which for  $\mu \neq 0$  is exactly the singleton  $\{\mu\}$  (`maxSlice_rayC`). That the device is faithful to the denotation is kernel-checked, hypotheses included, in module `SuFunctor.Adequacy.Envelope`: the two verdict readings agree kind by kind — a lower-kind (slice-reading) verdict against the ray is the verdict at  $\mu$  (`satCredal_lower_rayC`), and an upper-kind (whole-set) verdict agrees between ray and slice for every *down-closed* constraint (`DownClosed`; event upper bounds qualify, with no hypothesis on  $\mu$ ). The boundary is part of the theorem, not a footnote: at  $\mu = 0$  the slice is *empty* — the bottom credal body, per Remark 9.16 — and ray and slice agree as raw constraints *only* there (`rayC_eq_singletonC_iff`): divergence is governed by  $\mu \neq 0$ , not by submass. Mixing the two readers is refuted as a theorem, not discouraged as a convention: reading a lower-kind atom with the whole-set reader refuses every positive threshold, for every  $\mu$ , the ray’s zero element being the universal refuter (`not_satCredal_upper_rayC_geC`). For the squares’ consumers the hypothesis discharges for free: a compiled stochastic frame’s law has mass one, hence is nonzero. The set-valued extension is kernel-checked in module `SuFunctor.Adequacy.EnvelopeUnion`. For a *family* of laws the set-valued presentation is the union of the members’ rays: radial and, for a closed family, itself a credal body, though in general *not convex*. Whether the closed convex hull is taken is a modelling fact, not a convention: an adversary with strategy access over the family can *mix*, and for such faces the hull is the achievable set — the correct denotation — while for a parameter fixed once and unknown the bare union is the correct denotation, and taking the hull would add mixtures the family cannot realize. The slice of the union always sits inside the family (`maxSlice_unionRays_subset`, hypothesis-free), and for a family of equal nonzero mass the slice is exactly the family (`maxSlice_unionRays`), equal mass being spent on cross-ray domination. Fixtures witness the hypothesis’s necessity: a *nonempty* all-zero family collapses its union to the bottom object with an empty slice, exactly as the single-ray boundary predicts, and the empty family yields the empty union, which sits below even bottom.

### 9.5.5 Gluing: The Imprecise Extension Problem

A System’s mechanisms hand the semantics *local* credal data — interval kernels, rate intervals, disturbance sets — on finite windows; the denotation must be a global object on records whose restrictions reproduce the local data. This is the Kolmogorov extension problem, transposed, and its imprecise answer stratifies along the record direction:

- *Existence and exactness, kernel-presented case.* When local data arrive as compact credal sets of transition kernels in the record direction — the shape discrete-time mechanism presentation produces — the glue exists with no topological hypotheses beyond that compactness, is computed by iterated marginal extension, and reproduces the local models on the nose: the Marginal Extension Theorem of de Cooman and Hermans [49] for imprecise probability trees, with backwards recursion as

its computational face. The on-the-nose verdict carries its scope wherever this book leans on it: discrete-time record posets, finite or discrete state, compact credal local sets, and Williams-coherent globals. Continuous-state and continuous-time mechanisms hand the semantics local data through their own doctrine presentations; their extension theory is named debt in [section 9.13](#), not a corollary of the kernel case.

- *Uniqueness fails — by design.* Many coherent global models share the same finite-window restrictions. The canonical choice is a universal property, not an isomorphism: the *natural extension* — the least-committal coherent glue, pointwise-smallest lower expectation at [Definition 9.24](#)’s stated scope, largest compatible set of models (convex as a theorem, not by fiat; see the definition). The slogan this makes precise carries through everything in [section 9.9](#): the model constrains the distributions; it does not select one.
- *Beyond the record direction, the flavour of coherence is a real choice.* For parallel cover shapes on infinite spaces, Walley-coherent independent products can fail to exist (Miranda and Zaffalon [121]); adopting Williams coherence repairs existence (De Bock’s independent natural extension), and this universe adopts Williams coherence as its default — a genuine doctrinal selection, recorded here, with no consequence at finite state where the flavours coincide.

**Definition 9.24** (Coherent lower prevision; natural extension). Let  $L$  be the linear space of bounded Borel gambles on  $\mathcal{X}$ . A functional  $\underline{P}: L \rightarrow \mathbb{R}$  is a *coherent lower prevision* when, for all  $h, g \in L$  and real  $\lambda \geq 0$ :

$$(W1) \quad \underline{P}(h) \geq \inf h;$$

$$(W2) \quad \underline{P}(\lambda h) = \lambda \underline{P}(h);$$

$$(W3) \quad \underline{P}(h + g) \geq \underline{P}(h) + \underline{P}(g).$$

Its conjugate upper prevision is  $\overline{P}(h) := -\underline{P}(-h)$ . An *assessment* is a pair  $(K, c)$  with  $K \subseteq L$  and  $c: K \rightarrow \mathbb{R}$  assigning claimed lower bounds — the local data a System’s mechanisms hand the semantics. Its *compatible set* is

$$M(K, c) := \{P \in \Delta(\mathcal{X}) : E_P(h) \geq c(h) \text{ for all } h \in K\},$$

and  $(K, c)$  *avoids sure loss* when  $M(K, c) \neq \emptyset$ . The *natural extension* of an assessment avoiding sure loss is  $\underline{E}_{K,c}(h) := \inf_{P \in M(K,c)} E_P(h)$ ; equivalently — exactly, for finite  $\mathcal{X}$ , by linear-programming duality — it is computed by finite positive combinations of assessment deficits. Universal property, with its scope stated in the same breath:  $\underline{E}_{K,c}$  is a coherent lower prevision dominating the assessment, and at finite  $\mathcal{X}$  it is the pointwise-smallest such functional outright — at infinite  $\mathcal{X}$  the countably additive envelope displayed here is least among the *countably-additive-envelope* lower previsions dominating the assessment, the classical unrestricted minimum being represented by finitely additive probabilities, per the agreement scope below; dually  $M(K, c)$  is the largest compatible set of models outright — the comprehension takes every compatible model, and no convexity clause appears. Its convexity is a *theorem*: each constraint  $E_P(h) \geq c(h)$  is affine in  $P$ , so the compatible set is an intersection of half-spaces with the simplex (and closed whenever the assessment’s gambles are continuous — expectation against a merely Borel gamble is not a weakly continuous functional, so closedness is a hypothesis at the standing generality, not a freebie). Least-committal lower prevision and largest compatible set are the same universal property read on the two sides of the envelope correspondence: the natural extension adds no commitment beyond what the assessments force.

*Remark 9.25* (Mechanization status of the envelope package; the partiality departures). Kernel-checked in this repository, at the finite-rational stratum (module `QtslAux.Imprecise.Credal`): the envelope face of the coherence axioms over credal sets presented as finite families — attainment of both envelopes, superadditivity of the lower and subadditivity of the upper, positive homogeneity, and monotonicity. Kernel-checked at the general carrier — an arbitrary measurable record space, countably additive models, bounded measurable gambles under the Bochner expectation (module `QtslAux.Imprecise.NaturalExtensionGeneral`): envelopes of arbitrary nonempty families of probability measures as coherent lower previsions (no convexity or closure of the family consumed); the compatible set, avoidance of sure loss, and the natural extension as the envelope over the compatible set, with the universal property at exactly the stated scope of [Definition 9.24](#) — least among the countably-additive-envelope lower previsions dominating the assessment (`natExtG_le_lowerEnvG`), the dominating-family hypothesis itself certifying avoidance of sure loss (`avoidsSureLossG_of_dominating`), so no separate feasibility hypothesis enters — together with the largest-credal-set dual, convexity of the compatible set in mixture form, and the definition’s closedness parenthetical

as a theorem: the compatible set is narrowly closed whenever the assessment's gambles are continuous. One storey up, where denotations are credal bodies rather than subsets of  $\Delta(\mathcal{X})$  (section 9.6), the same universal property is available with no convex vocabulary at all: an assessment's constraints have walls, the natural extension is the *join of those walls* in the pointwise order, and its body is the *largest compatible body* — the radial compile of the largest compatible set of laws. For assessment-shaped (gamble-bound) constraints this body is convex by the affinity theorem above, read through the compile; for structured constraints the same join is the right object and is genuinely non-convex — an independence assertion's body is a credal body and not a convex one (the kernel-checked witness of the epistemic-states module: the diagonal mixture of two deterministic independencies is perfectly correlated), which is why citizenship in this universe is lower semicontinuity and never a shape axiom. The distinction is invisible at the lower-prevision stratum by construction — expectation is affine in the model, so a body and its closed convex hull have the same lower envelope on every gamble — and taking the hull is exactly *demonic-choice* semantics: the correct reading where an adversary may mix admitted laws, and a canonical representative rather than a definitional ingredient everywhere else. The classical “largest credal set” formulation is thus recovered, not presupposed: it is the demonic representative of the body-level universal property. The point-free face of envelope coherence — the superlinear class closed under lower envelopes, over gambles in sublevel presentation with the Choquet pairing — is kernel-checked in the point-free tower (`Pointfree.Prevision`). Kernel-checked at the finite stratum, where the claims themselves are finite (finite record spaces, real scalars; module `QtSLAux.Imprecise.NaturalExtension`): the sup-of-deficit-combinations display as exact linear-programming duality, alongside the sure-loss alternative; and the finite envelope theorem — every coherent lower prevision on a finite record space is the lower envelope of its credal set, in both the attained form and the envelope display — the separating engine, one invocation powering the package, being sublinear Hahn–Banach extension. At infinite  $\mathcal{X}$  the classical envelope theorem represents coherent lower previsions by *finitely additive* probabilities; the countably additive envelope is this book's definition, and the identification of the two representations is used only inside the finite-state agreement domain — beyond it, named debt. *Partiality departures, computed*: over the maximal slice of a submass-admitting credal body, (W2) and (W3) persist verbatim, but (W1) weakens to  $\underline{E}(h) \geq \min(\inf h, 0)$  and constant-additivity fails by exactly the leaked mass — deliberate, and why the axiomatic notion is stated on the full-mass stratum, where the classical theory is recovered exactly. The leak-aware safe-side accounting is kernel-checked in this repository (module `QtSLAux.LeakAware`): the mass-split union bound, the per-element and envelope forms of the safe-side subtraction (for a partial model  $P(\text{safe}) = P(1) - P(\text{bad})$ , not  $1 - P(\text{bad})$ ), the full-mass recovery of the familiar  $1 - V(x_0)$  floor, and a total-leak counterexample certifying that the naive floor is *unsound* for submass models.

### 9.5.6 Agreement, and the Attitude Operator

**Agreement.** The scope first: the agreement theorems of this paragraph are proven for finite state spaces in discrete time; their continuous-state and continuous-time lifts are named debt, and certificate soundness (which needs only a per-element argument, section 9.12) does not wait on them. Within that scope, the global object admits three constructions that are not obviously equal: the game-theoretic upper expectation of Shafer and Vovk [218] (an infimum over hedging supermartingales), the axiomatic most-conservative extension of T'Joens, De Bock, and de Cooman [229], and the measure-theoretic envelope over all compatible precise processes. The agreement theorems state that the three coincide on monotone limits of finitary gambles and on bounded-below Borel path functionals — and the specification logic's query class sits inside that domain by construction. This book works with the game-theoretic presentation; the reason is an adapter fact, stated with the rest of the adapter material where it belongs (section 9.12): certificate rows enter the defining infimum *definitionally*.

**The attitude operator.** Certification is pessimism ( $\underline{E}$  of goodness-valued functionals; equivalently the  $\bar{E}$  of the loss). Design exploration wants the other end too, and occasionally a weighted blend — Hurwicz's optimism–pessimism criterion [119], transposed: for  $\alpha \in [0, 1]$  and a *bounded* path functional  $h$ ,  $H_\alpha(h) = \alpha \bar{E}(h) + (1 - \alpha) \underline{E}(h)$ , stated for goodness polarity so  $H_1$  is pure best-case optimism and never a guarantee quantity. The endpoints compose along records for the natural-extension denotations mechanism presentation produces (the marginal-extension tower property); interior  $\alpha$  does not, and the failure is an exact-rational fact — a two-stage interval-kernel chain realizes root-blend  $\frac{15}{32}$  against stagewise-blend  $\frac{14}{32}$ , and a second instance reverses the sign, so composed interior- $\alpha$  scores are neither sound bounds nor reliable estimates. The design consequence is a restriction the grammar adopts wherever

the operator appears:  $H_\alpha$  is a *root-only* query operator with no congruence rule, evaluated by the two passes that do compose and mixed once at the root, and any verdict at  $\alpha > 0$  renders as a design score, never as a guarantee. The structural derivation sits beside the kernel-checked counterexample: an interior blend mixes a refinement-monotone and a refinement-antitone quantity, so it is not monotone in the universe's refinement order and therefore not an entailment-shaped operator at all — the root-only restriction is the order speaking. Attitude lives in the query. Systems carry none.

## 9.6 The Hyperspace Storey

The universe of [section 9.5](#) is a space of functions with a pointwise order. Everything the specification logic will ask of the universe — connectives, entailment under a context, case analysis, and the composition calculus's fibres — lives one storey up, on *sets* of denotations, and this section fixes that storey: the hyperspace, the passage from heights to bodies, and the two facts that organize all later use — from this storey up the order of the universe is inclusion, and Systems enter as singleton elements.

**From heights to bodies.** A belief  $\sigma$  on the probability face compiles to its *body*: the closed radial subset of the subprobability carrier admitting each law  $\mu$  at every scale up to its grade,  $S(\sigma) = \{\gamma\mu : \gamma \leq e^{-\sigma(\mu)}\}$  — Definition 9.17's compile, kernel-checked at the general carrier, with the finite stratum carrying both exact presentations (Remark 9.18). Under the compile the pointwise order on the radial stock becomes inclusion of bodies, belief addition becomes the fibrewise grade product, and the height calculus of [section 9.5](#) is available, on that stock, as a calculus of closed radial sets: one structure with two interchangeable presentations, heights for arithmetic, bodies for topology. The *hyperspace* of the storey is the space of closed subsets of the subprobability carrier under the Fell topology of [section 9.4](#) — compact with no hypotheses on the carrier, and the home of every body, since bodies are closed by definition. And the storeys compose: the record storey already did its work in the Fell topology, so a window's record space arrives *compact* metrizable ([section 9.4](#)), and the subprobability carrier over it is compact Hausdorff (on a compact carrier the weak and vague readings coincide, and the carrier is weak-star closed in the unit ball — Alaoglu, standard); on the finite stratum it is the simplex, compact on sight. On a compact Hausdorff carrier Fell and Vietoris are *one* hyperspace topology — the Fell form agrees with the nonempty-compacts Vietoris presentation, kernel-checked at exactly those hypotheses (`fell_eq_vietoris`) — and the nonempty bodies are compact, so that presentation is the exact stratum's home for the class machinery below. The machinery itself no longer needs the compactness mediation: crescents, their two faces, local closedness, the constructible algebra, and the judgment transport are kernel-checked at the general carrier directly, over the Fell hyperspace of an arbitrary topological measurable record space (`SuFunctor.Universe.General.CrescentStratum` — both crescent faces ride the hit-open subbasis Fell and Vietoris share: the containment face closed because its complement is a hit of an open, the escape faces hit-opens outright), with the compact/Vietoris presentation surviving as the exact-collapse special case. For a carrier that arrives noncompact, the one-point-compactification mediator,  $CL(Y) \cong \{B \in \mathcal{K}(Y^+) : \infty \in B\}$  (Remark 9.11), still carries the Fell form into the compact presentation where the exact stratum wants it.

**The order at this storey is inclusion.** On bodies the universe's order reads  $S(f) \subseteq S(h)$  iff  $f \geq h$  (Definition 9.17), and from here up — bodies in classes, classes in classes, fibres over the wiring base — every comparison this universe supports *is* an inclusion. This is the form of the order the specification logic's judgments will consume when later chapters interpret the logic here: not a new relation at each storey, but one order — pointwise on beliefs, exchanged by the compile with inclusion at the hyperspace, read off the fibre carriers of the composition construction unchanged ([section 9.9](#)).

**Systems are singleton elements.** A System enters the storey as the singleton  $\{S(\sigma)\}$  of its body — an *ideal point* of the hyperspace. The name records a theorem, not a convention — singletons are not spec-definable (no formula of the spec syntax denotes a one-point class: `singletons_not_definable`, with its upper-open companion), so a precise refinement can never be pinned by Spec syntax and selection data is certificate content, never formula content. And the embedding leaves no residue: membership of a body in a class is inclusion of its singleton in the class — the fibre order of [section 9.9](#), at one window (`idealPoint_le_iff`) — so “Systems are singleton elements of the hyperspace” is the exact sense in which one order serves every boundary: body above body, singleton inside class, class inside class.

## 9.7 The Fibre of Specs: Constructible Classes in the Hyperspace

A Spec needs more than one body at a time. The logic conjoins Specs, disjoins them, asks whether one entails another under a context, and wires the Systems they govern into larger Systems. Each of those acts consumes classes of bodies rather than single bodies, and the classes must survive all of them at once. This section fixes the classes. The atoms of the stratum denote *crescents*: one closed containment face, cut by finitely many open escape faces. Compound Specs denote finite unions of crescents, which live in the *finitary constructible algebra* of the hyperspace. Entailment denotes inclusion of classes, and a finite blocking criterion decides it. Every demand the logic places on this structure is discharged as a theorem, and the section ends where the theorems currently end: at the algebra’s boundary, where the attitude classes of [section 9.5](#) provably live outside it, and where a completion question stands open.

What a logic may ask of its classes was settled long before this book. Categorical logic, since Lawvere, reads predicates as objects of fibres over a base of contexts and states what each connective demands [155, 156]. Substitution must act functorially along the maps of the base. Entailment must be the order of each fibre, and posets suffice for a proof-irrelevant sequent logic. Conjunction and disjunction must denote fibrewise lattice structure, preserved by reindexing, with the distributive law available to the context-carrying elimination rules. Quantifiers, where a logic has them, must be adjoints to substitution, subject to Frobenius reciprocity and the Beck–Chevalley condition. Jacobs gives the systematic dictionary between fragments of logic and the fibred structure each fragment demands [124]; Pitts surveys the same territory [199]; Melliès and Zeilberger reconstruct Lawvere’s setting bifibrationally [179]. The Spec connectives speak the *coherent* fragment: finite conjunction, finite disjunction, top and bottom; no negation, no implication, no quantifier former. Its categorical model theory is classical [169], and the match is designed rather than residual. Coherent sequents are the sequents the blocking criterion below decides with finite certificate data — domination rows, selections, choice bytes — and the same fragment, in its implicational dress, is the one the Geolog engine’s chase evaluates ([chapter 5](#)). Certifiability chose the fragment; the tradition then says what the fibre owes.

The debts are paid in order. Atoms and their classes come first, together with the polarity discipline that replaces any monotonicity intuition a reader might import. The disjunction theorem then removes the one degree of freedom an interpreter might believe remains. The blocking criterion decides entailment. Three refusals close the account: negation, refused by the carrier; quantifiers, declined at this stratum while the genuine adjoint lives one storey down; and attitudes, refused by a theorem. Beneath the atoms, the graded layer explains why graded judgments demand no graded classes, and a final subsection states the completion question the refusals leave open. On evidence, one standing note: the coherence claims of this section cite receipts from multiple proof-checking kernels (Lean 4, SafeVerify, and nanoda; [section 9.13](#) states what each checks), the receipts are re-runnable, and the claims that do not yet have them are labelled rather than blended in. This section is where that discipline proved its worth — the design-record instance after Theorem 9.28 tells the story.

### 9.7.1 Atoms: Crescents

**Definition 9.26** (Spec atom, and its crescent). A *spec atom* is a pair  $(u, \mathcal{D})$ : a *safety face*  $u$ , one member of the universe, the atom’s floor; and a finite *liveness set*  $\mathcal{D}$  of members, its escape demands. The atom’s class in the hyperspace is its *crescent*,

$$\text{cres}(u, \mathcal{D}) = \{K \mid K \subseteq S(u)\} \cap \bigcap_{v \in \mathcal{D}} \{K \mid K \cap S(v)^c \neq \emptyset\},$$

the bodies contained in the safety face’s body that escape every liveness demand’s body. The kernel form is `SuFuctor.Universe.crescentClass`.

The two kinds of face quantify in opposite directions, and the opposition is the atom’s content. The containment face demands that *every* admitted law stay within the floor’s body; it is the safety half of the atom, and the pessimistic pass of [section 9.5](#) discharges it, by domination against the worst case. Each escape face demands that *some* admitted law leave the demand’s body; it is a liveness conjunct, and the optimistic pass discharges it, by a witness at the best case. One atom thus couples a  $\forall$ -polarized face with finitely many  $\exists$ -polarized ones. This is the liveness repair of [section 9.5](#) at the right altitude, and the leak asymmetry established there governs how partiality counts on each face.

Topologically, a crescent is one Vietoris-closed containment face cut by finitely many lower-open escape faces, hence a *locally closed* subset of the hyperspace (`isLocallyClosed_crescentClass`, in the locally-closed layer at the general carrier). The shape is kindred to the hit-and-miss generators of [section 9.4](#) — one closed demand, finitely many open ones, the cover-modality geometry — though the two families are not one: the capacity generators hit basis opens and miss compact closures, while a crescent’s closed face is a containment. The kinship is what matters. The spec logic’s atoms, the carrier’s determination principle, and the checker’s test regions speak one geometry, at two floors of the same tower.

The transports between an atom’s presentation and its class are exact: a body lies in the crescent with empty liveness set precisely when its belief dominates  $u$  in the universe’s order, and inclusion between safety-only crescents reverses the pointwise order on their floors. The kernel forms are `compileNC_mem_crescentClass_iff` and `compile_subset_compile_iff`.

**Graded reach-avoid: the atoms, in control-theoretic dress.** The atoms are a familiar object of control theory wearing graded clothing. Call a spec atom with one *genuine* liveness demand — liveness set  $\{\ell, \top\}$ , the properness mark carried along structurally — a *graded reach-avoid* atom. Its judgment demands that the system dominate the safety floor  $u$  (graded avoidance: the floor prices every admitted law rather than merely forbidding a region) and dip under the mark  $\ell$  (graded reach: some admitted law strictly undercuts the demanded bar); the kernel form is `mem_modelClass_reachAvoid_iff`. With wall data on both faces — a crisp safe set  $S$  and a crisp target  $T$  — the judgment becomes literally the classical possibilistic reach-avoid demand, *exclude  $S^c$ , keep some state of  $T$  possible* (`coupledSat_crispRA_iff`), the specification studied as a decision problem since [228] and still the benchmark object of certificate-based stochastic verification [35, 244]. The generalization is strict already over a one-point carrier, and at the algebra level rather than atom by atom: no finite  $\vee/\wedge$  combination of crisp reach-avoid classes separates the constant systems 1 and 0 — every wall admits both or excludes both — while a graded floor does (`exists_genClosure_reachAvoid_not_crispGenerated`). The stratum is then *exactly* the completion of graded reach-avoid under the calculus’s two connectives: a class is constructible if and only if it is a finite disjunction of finite conjunctions of graded reach-avoid atoms, kernel-checked at both strata (`genClosure_reachAvoid_iff_exists_specDnf` on an arbitrary carrier; `genClosure_reachAvoidCres_iff_exists_specDnf` in the hyperspace, with constructibility of the generated algebra as `isConstructibleUnion_of_genClosure_reachAvoidCrescentsLsc`). The decomposition inside a single atom is conjunctive, exactly: a liveness *set* is the intersection of the singleton-liveness atoms sharing its floor (`modelClass_eq_iInter_reachAvoid`, `crescentClass_eq_iInter_reachAvoid`), and the disjunctive reading is refuted outright — one unsatisfiable demand empties an atom but not the union of its singletons (`exists_modelClass_ne_iUnion_reachAvoid`). Disjunction of liveness demands, for its part, never needs the class level at all: within one atom it is mark-join (`dip_sup_iff`), so the  $\vee$  the completion spends is spent entirely on unions of classes. Two boundary readings earn the “exactly.” The empty disjunction is generated — the false Spec, the empty class — while the empty conjunction is deliberately not: no constructible class is trivially true, because every presented atom carries the properness demand (Remark 9.31), and that same mark is what closes the completion using *binary* conjunction alone, since every liveness set is nonempty and its intersection is anchored at the atom’s own  $\top$ -mark. For a reader arriving from the reach-avoid literature the translation reads: a Spec of this logic is a finite monotone combination of reach-avoid demands whose avoidance is priced rather than binary and whose reach is a strict undercut of a graded bar — and the wall fragment ([section 9.12](#)) is the crisp sublanguage through which checked verdicts embed.

## 9.7.2 Classes: the Constructible Algebra

**Definition 9.27** (Spec class, and the constructible sets). The *spec class* of a compound Spec in disjunctive normal form — a finite family of atoms  $(u_i, \mathcal{D}_i)_{i < n}$  — is the union of its disjuncts’ crescents,  $\text{dnf}((u_i, \mathcal{D}_i)_i) = \bigcup_{i < n} \text{cres}(u_i, \mathcal{D}_i)$ . A subset of the hyperspace is *constructible*, in the finitary sense, when it is a finite union of locally closed sets (`SuFunctor.Universe.IsConstructibleUnion`). The classes of the stratum are the constructible sets.

Two boundaries in that definition are deliberate. The notion is finitary rather than spectral, and the mechanization defines it directly instead of reusing a library notion: on a connected compact Hausdorff hyperspace the spectral-space constructible algebra, generated by compact open sets, degenerates to the trivial one, while the finitary algebra is the one the spec syntax generates. And the family is closed under the operations the calculus performs: finite unions by definition, finite intersections because crescents

intersect to crescents (`crescentClass_inter_crescentClass`) and intersection distributes over union by the powerset frame law (`inter_dnfClass_append`). Top and bottom are the trivial atom's class and the empty disjunction. Systems enter the stratum as the ideal points of [section 9.6](#): the singleton class  $\{S(\sigma)\}$  of a System's body, spec-undefinable, with membership read as inclusion.

What makes this algebra *the* fibre, rather than one candidate among several, is transport. The composition calculus of [section 9.9](#) reindexes classes along wirings, and the transport dictionary makes reindexing *preimage* at the body level (`compile_pullPen`). Preimage respects both kinds of face — the pullback of a pointwise join is the join of the pullbacks, so atom-level transport commutes with atom conjunction definitionally — and distributes over the constructible unions (`transportClass_union`), which, for subobject fibres, is the coherent-category axiom that finite unions be pullback-stable. So the fibres are posets under inclusion, the one order of the universe from the hyperspace storey up; the connectives denote fibrewise lattice structure; and reindexing preserves it by variance rather than by axiom. The adjudicated boundary of the transport claim — atom-level transport against image transport, exact along surjections, genuinely divergent off them — is [Remark 9.49](#), and the double Grothendieck assembly of [section 9.9](#) packages the whole, every obligation kernel-checked, with the window-indexed families of these classes as its fibre data. The definite article is earned on two sides: this is the least family that contains the atoms and holds the connectives, and no larger family currently carries the assembly's kernel-checked functoriality. Whether a larger one can is the closing subsection's question.

### 9.7.3 Polarity, not Monotonicity

Entailment denotes inclusion, and inclusion is an order; a reader may therefore expect the classes to sit monotonically in the universe's *other* order, refinement — every class an up-set or a down-set of better-and-worse systems. They do not, and the failure is structural. A containment face is downward closed: shrink a body inside the floor and it stays inside. An escape face is upward closed: enlarge a body that meets an escape region and it still meets it. A crescent with both kinds of face genuinely present is the intersection of a down-set with finitely many up-sets, so it is neither, and unions inherit the mixture. Refining a System preserves its safety verdicts and threatens its liveness verdicts; coarsening does the opposite. Satisfaction is not monotone along refinement in either direction, and no repair should be attempted, because the mixture is what a coupled safety–liveness demand *means*.

What composes is polarity. Every literal of a presented Spec carries a face. Each face is discharged by one envelope pass alone: the floor by the pessimistic pass, each escape by the optimistic pass, and the passes compose along records separately (the marginal-extension tower property of [section 9.5](#)). What a literal returns is a verdict — one Boolean, with the face's certificate behind it — and verdicts are data. The connectives combine finished verdicts and never reach inside a face, so a compound judgment survives wiring face by face even though no monotonicity survives at all. In brief: *a Spec mixes verdicts*. The one operator in this book that mixes the passes themselves, before any verdict is taken, cannot live in this stratum; that refusal now has a theorem, and it is the subject of the attitude subsection below.

### 9.7.4 The Disjunction Theorem

Any interpretation of the logic into this stratum will read formulas as constructible classes, entailment as inclusion, and conjunction as intersection. One choice appears to remain: which class interprets  $\Phi_1 \vee \Phi_2$ . The rule catalogue's disjunction elimination, in its context-carrying core form, demands of an interpretation  $J$  of  $\Phi_1 \vee \Phi_2$  (with  $A = \llbracket \Phi_1 \rrbracket$ ,  $B = \llbracket \Phi_2 \rrbracket$ ):

$$\forall \gamma, \psi: \quad \gamma \cap A \subseteq \psi \longrightarrow \gamma \cap B \subseteq \psi \longrightarrow \gamma \cap J \subseteq \psi.$$

**Theorem 9.28** (Union is forced). *Over inclusion-ordered class fibres, on any carrier:*

1. *contextual disjunction elimination is valid for all contexts  $\gamma$  and conclusions  $\psi$  if and only if  $J \subseteq A \cup B$ ;*
2. *adding soundness of the two introduction rules ( $A, B \subseteq J$ ), the conjunction holds if and only if  $J = A \cup B$  exactly;*
3. *every strict inflation is refuted uniformly: if  $A \cup B \subset J$  strictly, there exist an explicit context and conclusion —  $\gamma$  any class meeting  $J$  off the union,  $\psi = A \cup B$  — under which both premises of the elimination rule hold and its conclusion fails.*

The proof is elementary (instantiate  $\gamma$  at the full class and  $\psi = A \cup B$  for the forcing direction; distribute intersection over union for soundness) — elementary the way a door with one key is easy to open: the fibre order leaves the interpretation of  $\vee$  *no freedom at all*. The tradition states the context-carrying elimination rule as a demand an interpretation must satisfy; over these fibres the demand has one solution, so the rule is not checked against a chosen semantics — it chooses the semantics. The kernel forms are `SuFunctor.Universe.ctxOrE_valid_iff`, which depends on no axioms whatsoever, pure constructive set logic; `orI_ctxOrE_valid_iff`; and `exists_ctxOrE_countermodel_of_ssubset`, the latter two within the development’s standard three axioms (section 9.13 names them).

Three consequences follow, in ascending order of consequence for this book.

*First, the availability problem is real, in-universe.* Locally closed classes are not closed under union, and not merely in general topology. Two spec-atom classes of the shape above — one closed atom, one escape atom, over a two-point outcome space — have a union that fails local closedness in the hyperspace, kernel-checked with an explicit convergence witness (`exists_union_crescentClass_not_isLocallyClosed`). A stratum of locally closed classes *alone* cannot hold its own disjunctions; and by clause (3) of the theorem, any attempt to stay locally closed by interpreting the join as a locally-closed *envelope* of the union manufactures its own countermodel. The constructible closure escapes both refutations, and it is not a closure operator at all: it enlarges the admitted classes until the union is native, adding no points to any join. On the constructible stratum the rule holds with equality and no side conditions. The class of the join is literally the union (`dnfClass_append`), conjunction distributes (`inter_dnfClass_append`), the conclusion is constructible (`isConstructibleUnion_dnfClass_append`), and contextual elimination is an instance of clause (1) (`ctxOrE_dnfClass`).

*Second, the design-record instance.* An earlier design of this semantics made convexity an admissibility condition of denotations. It stated no semantics clause for spec disjunction — but inside a universe of convex denotations the only candidate join of two spec denotations is their envelope, the greatest convex lower semicontinuous minorant, whose body is a hull; and a hull inflates the union whenever the disjuncts are not nested, so clause (3) manufactures the refutation. Concretely, over one probability coordinate  $x$ , the walls  $A = [0, \frac{1}{3}]$  and  $B = [\frac{2}{3}, 1]$  with context  $\gamma = \{\frac{1}{2}\}$  refute contextual elimination against the envelope reading: both premises hold vacuously, since the context meets neither wall, and the conclusion fails because the hull swallows the context. The refutation, found in this development’s design record against the reading that admissibility condition forced, is thereby an *instance of a kernel-checked schema* rather than a fact about convexity: convex hull, locally-closed envelope, and any future closure operator fail the same rule by the same mechanism, and plain union is the reading left standing. The repair cost nothing that was true — every verdict of the wall fragment transports to the class stratum through the crescent embedding unchanged. And the refuted candidate is itself mechanized at the standing generality rather than surviving as prose (`SuFunctor.Universe.HullClosure`): over complete second-countable metric carriers, binary hulls of closed sets of laws are narrowly closed with no closure bar (`isClosed_pairHull`, `isClosed_binaryHull` — the mechanism is the cone’s own, with no linear-space analogue: a fixed limit law manufactures its compactness, tightness of the one measure plus positivity of the decomposition, no cancellation between arms), and the quasiconvex coproduct is *levelwise exact*: its sublevels are the plain hulls of the sublevel unions, with none of the  $\varepsilon$ -regularization the general-locally-convex literature would demand (`sublevel_qCoproduct_eq`, `greatestness` as `qCoproduct_le_min` and `le_qCoproduct_of_forall_mixConvex`). The join the elimination rule forbids is thus refuted as a fully mechanized object, at full strength: the hull inflates the union not because its topology misbehaves — it provably does not, on this cone — but because inflation is what a hull *is*.

*Third, the two disjunctions separate, and the calculus’s  $\vee$  is the union one.* At the functional level the pointwise minimum is the lattice join of demands, and against single-functional conclusions it validates the elimination rule (the height lattice is a frame). The class stratum’s grammar is strictly richer — conclusions may be classes — and against class-valued conclusions the minimum reading breaches: the body of  $\min(\sigma_x, \sigma_y)$  for two point-mass walls contains the two-point *hedger*  $\{x, y\}$ , a body committed to the union without committing to either disjunct, so the containment class of the min strictly inflates the union of the containment classes (kernel-checked: `boxClass_union_ssubset`, with the resulting elimination countermodel at an entailment-expressible conclusion, `exists_ctxOrE_countermodel_body_reading_carrier`). The functional-level minimum survives as what it is, the join of the height lattice, sound for the single-conclusion fragment; the specification logic’s disjunction is the class union, where the richer grammar’s elimination rule demands it. What the union reading returns is worth naming: the *disjunction property* at the system boundary.

Membership of a body in a joined class is membership in one disjunct's class (`mem_dnfClass_append_iff`), so a System inside a disjunction is inside a disjunct, and a certificate of the membership carries the choice of disjunct as one byte of certificate data — restoring, at the semantic boundary, the constructive reading the functional level provably lacks.

*Remark 9.29* (The three layers of the elimination rule). The rule's status is settled at three independent layers, and the layers do not lean on one another. *Proof theory*: the context-carrying form is not derivable from the context-free core — every core rule is sound over every lattice interpretation, and the modular lattice  $M_3$  refuses the distribution the derivation would need; a kernel-checked interpretation argument, untouched by any semantics. *Chart semantics*: inside the convex chart the rule is refuted (the design-record instance above), which retrospectively explains the underderivability, since every other core rule is convex-chart-sound and a derivation would have transferred a chart-validity the rule lacks. *Class semantics*: over the constructible stratum the rule is valid with equality, and inflation-of-union is provably the only failure mode (Theorem 9.28). The catalogue's decision to carry the context-carrying form as a core rule is thereby vindicated three ways: primitive because underivable, valid because union, and necessarily primitive because its validity is what the convex chart cannot supply.

### 9.7.5 Inclusion, Negation, and Properness

Inclusion between constructible classes — the relation the logic's entailment sequents will denote — is decided by a finite *blocking criterion*, kernel-checked in the locally-closed layer (`coupled_union_refinement_iff`). A DNF-to-DNF inclusion holds iff every *selection* (one demand chosen per conclusion disjunct) is *blocked* by a premise-side domination. That is a quantifier alternation over finite index sets whose leaves are pointwise domination rows between members — certificate-shaped throughout: domination rows plus, per disjunction, the choice bytes above. The criterion is sound and complete on the stratum with no satisfiability side conditions; inconsistent premises self-block, so *ex falso* is derived rather than assumed. (At the presented stratum the properness reading below sharpens the boundary behaviour: every presented atom carries the properness demand, so the everywhere-infinite member belongs to *no* presented class at all, `top_notMem_modelClass`, rather than sitting vacuously in conclusions.) Two calibration facts bound the completeness claim: the naive rule pair that reads only per-disjunct domination without selections is incomplete, witnessed by a floor-raising inclusion, and refinement of the liveness sets is essential (`exists_naive_cover_incomplete`, `exists_essential_floor_raise`). The packaging of the criterion as a two-species sequent calculus — membership sequents and inclusion sequents with structural rules and admissible cut — is an obligation recorded in the ledger; the criterion the calculus would organize is kernel-checked.

*Remark 9.30* (Negation, and a boundary the class algebra makes easy to trip). The constructible family is closed under complement (the complement of a locally closed set is the union of an open and a closed set), so the class *algebra* is Boolean, and a future editor might read that as licence to complete the logic with a negation-former. The boundary stands, and its provenance is the carrier rather than the algebra: on submass carriers the mass identity fails —  $\mu(A)$  does not determine  $\mu(A^c)$  when mass may leak — so the complement of a wall is not the wall of a complement, event-level duals do not lift to denotation-level duals, and the typing rejections the grammar carries are theorems of this universe, not conservatism. Set-theoretic availability of complements at the class stratum is not semantic availability of a negation-former one floor down; the orientation-paired judgment kinds (upper and lower probability atoms) are row-level de Morgan bookkeeping, the sound residue of the failed duality, and they lose exactness only where double negation genuinely loses mass.

*Remark 9.31* (The properness presupposition, adjudicated). One semantic decision at this stratum was long held open: whether membership of a body in an atom's class *presupposes properness* — so that membership additionally asserts that the belief is finite somewhere, the everywhere-infinite denotation belongs to no atom's class, and *ex falso* inverts at the system boundary — or whether bare safety exists, with vacuous membership quarantined by explicit properness certificates where a rule needs them. The presentation stratum decides it, structurally, for the properness reading (*option A*): every presented atom's liveness set contains the properness demand — the mark  $\top$ , whose escape face a body meets exactly when it is proper — so an empty liveness set is unrepresentable rather than merely forbidden, the vacuous atom is  $(0, \{\top\})$  (exactly the decoration unit of [section 9.9](#)), the inconsistent system belongs to no presented atom's class, and *ex falso* inverts at the system boundary by construction. The inversion is located, not blanket. An atom's

safety containment holds at the bottom body for every floor (the axioms force  $0 \in S(u)$ , so  $\{0\} \subseteq S(u)$ ), and what refuses is exactly the escape clause — the existential conjunct every liveness demand carries, which the zero measure, a member of every demand’s body, can never witness. An infeasible system thus satisfies every safety face and escapes no liveness demand (the envelope stratum’s verdict profile, Remark 9.16); its exclusion from every presented class is the conjunction of those two one-sided verdicts — properness being the liveness demand every presented atom is guaranteed to carry — not a satisfaction collapse in either direction. The decision cost no existing result. The blocking criterion, the disjunction theorem, and the class algebra were stable under both readings — under the properness reading each liveness slot simply carries one more demand, which is literally what the presentation’s atoms now do — and the general hyperspace machinery underneath (crescents at arbitrary liveness sets) is untouched, which is why every verdict transported unchanged.

### 9.7.6 The Declined Quantifier

One demand of the dictionary this stratum deliberately declines: there is no quantifier former on the classes. Binding lives elsewhere in the universe. Records carry the variables (section 9.3); the certificate stratum’s shape-indexed families live on the functorial plates of Remark 9.42; and the substitution that quantifiers would be adjoint to belongs to the base — marginalization of joints along wire maps (Definition 9.41).

The existential the tradition asks for does exist, kernel-checked, one storey below the classes. Hiding a wire is the lower-semicontinuous envelope of inf-projection along the visible marginal, and against every citizen of the universe it is adjoint to belief pullback on the nose:  $\varphi \leq \text{hide}_p \sigma$  iff  $p \circ \varphi \leq \sigma$  (`le_infProj_iff`, `le_hide_iff`; Remark 9.43). Read in the entailment order, which opposes the pointwise order (section 9.6), this is Lawvere’s  $\exists_p \dashv p^*$ .

Frobenius reciprocity holds in the lax direction the formalities supply. For a citizen  $\psi$  of the visible carrier,  $\text{hide}_p \sigma \vee \psi \leq \text{hide}_p(\sigma \vee p^* \psi)$ , and likewise with  $+$  in place of  $\vee$  — either conjunction the storey speaks (`hide_sup_le`, `hide_add_le`). The comparison is strict: a kernel-checked witness on the escaping-mass family exhibits citizen beliefs for which conjoining-then-hiding and hiding-then-conjoining genuinely differ (`exists_lowerSemicontinuous_hide_add_ne`). The mechanism is the envelope step of the repaired existential. The envelope of a wall is the wall of the closure (`lscEnv_charFn`), so hiding adds the boundary values the visible image approaches but never attains, and a belief vanishing exactly at an added point detects the addition. The gap is visible at judgment resolution — a constant specification is dominated by one side and not the other (`exists_judgment_separating_hide_add`) — unlike the envelope itself, which changes no judgment. Under the inf-compactness certificate of Remark 9.43 the certificate survives conjunction with a pulled-back citizen, the reflector idles, and Frobenius reciprocity holds with equality (`hide_sup_comp`, `hide_add_comp`). Where marginalization is exact, quantification commutes with contexts on the nose; off the certificate, the fibred existential is genuinely lax — a fact the logic observes, not a packaging debt.

What is not claimed is the class-stratum packaging of that adjoint: a fibred existential on constructible classes, with Frobenius reciprocity over contexts and Beck–Chevalley squares over the site. At a quantifier-free stratum the Beck–Chevalley condition, governing as it does the commutation of quantifiers with substitution, has nothing to govern. The mechanized seam facts already mark where such a claim would have to be earned: escape witnesses die off the range of a non-surjective transport, and image transport leaves the constructible stratum (the saturation residue of Remark 9.49) — and images are what existentials are made of. The ledger records the obligation under its own name, the image-preimage adjunction on class fibres (section 9.13).

### 9.7.7 Attitude Classes: Outside, by Theorem

The refusals so far were designed; this one is proved. Recall the attitude operator of section 9.5: Hurwicz’s optimism–pessimism blend [119],  $H_\alpha(h) = \alpha \overline{E}(h) + (1 - \alpha) \underline{E}(h)$ , admitted into the grammar as a root-only query with no congruence rule, because interior blends fail the tower property and are not monotone in the refinement order (the exact-rational counterexample and the order-theoretic derivation both live in that section, and the specification language records the restriction, §14.10.18). That settled the operator’s grammar. It left a class-stratum question open. The *attitude class*  $\{K \mid \vartheta \leq H_\alpha(h)(K)\}$  is a definite subset of the hyperspace like any other, and nothing yet stops a reader from asking whether some Spec — perhaps an ingenious compound one — denotes it. The answer is no, and the reason is a

Figure 9.3: Why no finite disjunction reaches a mixed attitude, drawn in the plane of the two envelope values  $(\bar{E}(h), \underline{E}(h))$ . Each admissible chord  $(a, b)$  contributes one crescent, which covers the closed quadrant above and to the right of its corner; chords are demands, so their corners need not be attainable pairs. The attitude class covers the half-plane above the chord line. Finitely many quadrants form a staircase, and the starred model sits on the line beyond every listed escape face: it meets the Hurwicz threshold and escapes every listed crescent (`finite_chords_strict`).

decomposition worth having in its own right.

Fix the exact stratum (finitely presented credal sets over finitely supported laws — the stratum where certificates live), a bounded claim  $h$ , and a threshold  $\vartheta$ . Call a pair  $(a, b)$  an *admissible chord* when  $\vartheta \leq \alpha a + (1 - \alpha)b$ . Each chord names one atom-shaped demand: an escape face at  $a$  — some admitted law prices  $h$  at  $a$  or better, the optimistic pass — and a floor face at  $b$  — every admitted law prices  $h$  at  $b$  or better, the pessimistic pass. The Hurwicz threshold holds precisely when some admissible chord's demand holds, because the attained pair  $(\bar{E}(h), \underline{E}(h))$  is itself an admissible chord (`hurwicz_ge_iff_exists_chord`); at the level of classes, the attitude class equals the union, over the admissible chords, of their crescents (`hurwiczSuperlevel_eq_iUnion_crescents`). An attitude class is therefore a disjunction of Specs — an *infinitary* one, indexed by a half-plane of chords.

Infinitary, and irreducibly so. For a genuinely mixed attitude,  $0 < \alpha < 1$ , no finite subfamily of chords yields the class: against any finite list of admissible chords, a two-point model sits on the Hurwicz line beyond every listed escape face, meeting the threshold while escaping every listed crescent (`finite_chords_strict`). Figure 9.3 shows the geometry. In the plane of the two envelope values, one chord's crescent covers a closed quadrant; the attitude class covers the half-plane above a line of strictly negative slope; and finitely many quadrants make a staircase, which never covers a sloped line. Since every Spec denotes a finite union of crescents, no Spec denotes an attitude class. The grammar's root-only restriction thus reappears at the class stratum as a theorem about denotations: the operator does not merely lack inference rules; the classes it carves lie outside the algebra every Spec inhabits.

The boundary has a one-line grammar: *a Spec mixes verdicts; an attitude mixes envelopes*. Each literal of a Spec consults one envelope pass and returns a Boolean, and the connectives combine finished Booleans, which is why compound judgments transport face by face.  $H_\alpha$  adds the two passes into one scalar before any verdict is taken, and the sum behaves as neither pass: it has no single polarity, so no one face discharges it; it is not monotone along refinement, so it is not an entailment-shaped operator; and it is not stable under composition, because the chord attained at the root re-chooses when kernels chain — which is what the tower failure of section 9.5 says, read through the decomposition.

What survives for certification is the chord itself. A floor certificate at  $b$ , an escape certificate at  $a$ , and the arithmetic check  $\vartheta \leq \alpha a + (1 - \alpha)b$  together discharge the threshold (`le_hurwicz_of_chord`); a certificate pair is a choice of disjunct. A finitely presented certificate layer for attitude thresholds therefore carries its chord as data and never enumerates the class — one more instance of a pattern this universe keeps producing: where a class refuses finite presentation, its certificates do not (compare the disjunction property's choice byte above, and the properness mark).

### 9.7.8 Beneath the Atoms: the Graded Layer

A crescent's faces test bodies, and a body is a belief's shadow. The compile of [section 9.6](#) sends each belief  $\sigma$  to the closed radial set of laws it admits at each grade. A *wall* — a  $\{0, \infty\}$ -valued belief — casts a crisp shadow, the set of laws it admits outright; a graded  $\sigma$  knows strictly more, namely how expensively each law is admitted. The atoms of this section consult shadows. So a fair question about the whole construction is whether graded beliefs eventually demand graded classes — some second fibre, richer than the constructible one, where soft judgments would live. They do not, and the exact stratum now carries the reason as a pair of theorems.

At the exact stratum a convex prevision arrives finitely presented: finitely many laws  $M_i$  with signed rational costs  $c_i$ , pricing a claim  $f$  at  $\max_i (E_{M_i}[f] - c_i)$  — the penalty-function representation (so named in that literature) of convex risk measures [79], restricted to finite presentations (penUpperE, with penLowerE its conjugate). The wall tier is the zero-cost face, definitionally (penUpperE\_zero\_cost), and the precise tier is the one-member face. The first theorem says the grades never leave the reach of the classes: the scalar is the finite Legendre transform of its own threshold profile — the map sending each affordability threshold  $t$  to the best expectation among members costing at most  $t$  — and the profile's data at each threshold is an ordinary credal set (penUpperE\_eq\_sup\_levelProfile). A graded judgment therefore unfolds into a family of possibilistic judgments, one crescent face per threshold, and the scalar folds back by the transform. The second theorem says composition respects the unfolding: belief kernels compose by an exact intertwining square whose cost law — costs integrate along the record — is forced by countermodels on either side (penUpperE\_compFam; the unweighted and the worst-case aggregations each break the square on a two-state witness).<sup>5</sup> These are theorems of the exact stratum — finitely supported laws, rational costs, where certificates live; the general-carrier belief calculus of [section 9.5](#) stands beneath them unchanged. The atoms stay possibilistic; the grades thread through them one threshold at a time; and the classes of this section carry the soft tier without gaining a single new former.

### 9.7.9 The Completion Question

Two pressures point at one enlargement. The attitude classes ask for unions of crescents over a compact index; the graded layer, read at every threshold at once, asks for level families of the same shape. Both land in the  $\sigma$ -completion of the constructible algebra: classes presented as directed unions of crescents over declared index families, with the index carried as data. Nothing wild lives there. Each candidate class is assembled from the same atoms as every Spec, and its certificates are already finite objects — a chord, a threshold, a pair of faces.

What is not settled is transport, and the chord decomposition says why the question has teeth. The constructible fibre's functoriality is a theorem because preimage acts on finitely many faces at once. An enlarged fibre would transport index families, and the transport is pointwise in the index: under composition the attained chord re-chooses, which is the tower failure again, now as a design constraint rather than a pathology. A completion that demanded one uniform chord would refute itself at the first kernel chain. The candidate discipline, stated here as design and not as artefact: admit closed classes that declare semicontinuity certificates for both envelope passes, and transport them only along wirings carrying both certificates — the two-pass evaluation of [section 9.5](#) made compositional. Whether the resulting fibre keeps the composition calculus's kernel-checked functoriality, and whether it is the largest fibre that does, are open questions; the closing ledger names them ([section 9.13](#)). Until they close, this book's judgments live on the constructible stratum, where every demand of this section is discharged by a theorem.

## 9.8 The Fibre Sheaf: Spec Classes over the Site

The class stratum of [section 9.7](#) was built at one window. Records live over a site, so spec classes do too, and this section fixes how: the classes of [section 9.7](#), window by window, assemble into a presheaf whose

<sup>5</sup>The tier's calculus holds a few further facts a practitioner will want. Convexity replaces coherence: a mixture of claims is overpriced by the mixture of prices (penUpperE\_mix\_le), while positive homogeneity genuinely fails off the calibrated face, by a one-point witness (penUpperE\_not\_posHomogeneous) — the tier is convex-prevision, strictly wider than Walley coherence. And the point-mass family with a pointwise gate prices claims as a max-plus contraction (penUpperE\_dirac\_family), the idempotent-integration reading that connects this layer to tropical dynamic programming.

sheaf-theoretic behaviour is governed by the carrier results of [section 9.4](#) — with one structural surprise, itself kernel-checked, about *which* window-indexed families are admissible.

**Window beliefs, and the variance of extension.** Over a window  $W$  and an instantaneous carrier  $X$ , the trajectory space is the record carrier of [section 9.4](#), taken at state fibre  $X$ :

$$\text{Traj}(W, X) := \text{CL}(\mathring{S}(W) \times X^+)_{\text{Fell}},$$

closed subsets of the stage-interior-times-state ambient under the Fell topology, with  $X^+$  the carrier with its cemetery adjoined —  $\mathbb{H}(W)$  itself when  $X$  is the window’s own state fibre. Functions  $W \rightarrow X$  embed by *graph-then-closure*,  $f \mapsto \text{cl} \{(t, f(t))\}$ : on the speed-bounded class the graph is already closed and the closure does nothing — the graph reading of [section 9.3](#), recovered as the special case — while at a jump the graph is *not* closed, and the closure charges the jump instant with both one-sided values: the closed-graph doctrine again, a jump multivalued at the moment it happens. The embedding is accordingly not injective on jump functions — two functions differing only in which one-sided limit they assign at the jump instant close to the same set — and that quotient is intended, not a defect: the closed set remembers every value the instant is honestly charged with and forgets the convention that chose among them. Window beliefs are beliefs over this carrier: functionals carried, in the working presentation of [section 9.5](#), on subprobability joints — probability joints over the cemetery-completed carriers — at the standing generality of [Definition 9.15](#); these are laws of exactly the kind the capacity presentation of [section 9.4](#) pins by countably many rational observations. The scalar stock of that generality is kernel-checked as stated — subprobability Borel joints over arbitrary measurable carriers, with pushforward, belief transport, weak continuity, and the lower-semicontinuity closure and attainment package (`SuFunctor.Plain.MeasJoint`; the composition tier below carries the details) — with the finitely supported joints of the exact stratum its kernel-checked sub-instance along the seam (`toMeas_push`); nothing in the stock reads how the carrier is presented, so it serves the Fell carrier and the function presentation alike. The window *assembly* is kernel-checked at both joint strata over the *function presentation* (windows as subsets of a stage type, trajectory carriers the graphs before closure): the extension calculus and the persistence discipline of this section replay verbatim over subprobability Borel joints, with measurability as the morphism datum — the presented carriers get the product  $\sigma$ -algebra, under which clipping and pointwise state transport are measurable outright, and the window-compositor exchange is one application of the base-free naturality core with both comparison squares discharged definitionally (`SuFunctor.Site.GeneralWindow`: `penExtM` with its presheaf laws, both exchange theorems, and the closure package for persistent families) — and the exact assembly is the general one’s kernel-checked sub-instance along the seam (`penExtM_comp_toMeas`, `IsPersistentM.seamRestrict`). The same assembly restated over the Fell carrier itself — Borel-on-Fell as the measurability datum, the carrier section’s clip as the restriction — is an open obligation of the closing ledger, not a receipt in hand; the restriction leg is not part of the debt, its measurability being a corollary of the landed Fell-continuity of clip-to-open ([Remark 9.11](#)). The descent results below were never joint-stratum-bound at all: their ambient is an arbitrary topological space (the class-descent module is fibre-class-blind), so no stratum scoping applies to them. Two boundaries are real and worth naming. The double-categorical *total* of the site-indexed decoration functor over a wiring base stays at the exact stratum — the finite state-family presentation discharges its comparison squares definitionally, and a measurable wiring base owes its own transport data first, the same residue one tier up as in [Remark 9.45](#). And the matching-fork witness below is stated at the exact stratum because nothing more is needed there: its trajectory carriers are finite, and over finite carriers every presentation collapses into every other — a finite Hausdorff ambient is discrete, so every graph is closed, graph-then-closure is the plain graph embedding and is injective, and the two joint strata literally coincide, the seam embedding being a bijection (`toMeas_surjective` with `toMeas_injective`) — so the fork refutes the strict discipline at the general stratum, and on the Fell carrier, in the same breath. Which *evaluation-level* claims complete across the seam by density — and which provably do not — is [Remark 9.33](#). For nested windows  $V \subseteq W$ , trajectories *clip* ( $\text{Traj}(W, X) \rightarrow \text{Traj}(V, X)$ ): intersection with the subwindow’s open band — the carrier section’s Fell-continuous restriction, at fixed state fibre the pure clip of  $\rho_u$ ), and the clip agrees with the function presentation through the embedding: clipping a closed graph over an open sub-band is the closure of the restricted function’s graph, because closure-then-intersect is relative closure over an *open* set — one more place the interior coverage earns its keep. Beliefs therefore *extend*: a subwindow demand  $u$  is read over the superwindow as “evaluate  $u$  on the clip” (`penExt` := precomposition of the joint pushforward along clipping; `SuFunctor.Site.penExt`, on the presented carriers). The variance is forced: a belief reads whole-window joints, and only the small-to-big

direction has a canonical trajectory map — a closed set clips canonically and extends non-canonically, so there is no restriction of beliefs. Their *bodies* restrict — that is the compile trade: heights extend along the site, bodies clip along the site, and the two motions are exchanged by the compile isomorphism. Both motions are used below, each on its own side.

*Remark 9.32* (Relations first; functions as a dense locus). The carrier just fixed takes closed *relations* as its primary objects, and the function layer enters as a distinguished locus rather than as the ambient notion — in three precise senses. The locus is *dense*: wherever the stage interior has no isolated points (every nondegenerate classical window), each nonempty basic hit-and-miss class contains the graph of a finitely supported single-valued function on a sub-timeline — one point in each hit region, off the miss compact, shared stages separated within the open regions — so every closed relation is a Fell limit of function graphs. Its calculus is a *restriction*: the window assembly above, kernel-checked today on the function presentation, is designed as the relational assembly read along graph-then-closure, and the relational form itself is the closing ledger’s Fell-carrier obligation, not a receipt in hand. And the correspondence-theoretic apparatus arrives with no added hypotheses: for a closed-valued map into the compact state fibre, lower hemicontinuity is continuity for the hit face and upper hemicontinuity is continuity for the miss face — compactness of the fibre is what turns a closed complement into a miss parameter — so hemicontinuity is the slice-wise reading of the topology the carrier already wears, not a regularity assumption on a new kind of object.

*Remark 9.33* (Density completion: what the exact stratum settles). The exact stratum invites a completion argument: finitely supported joints are narrowly dense in the subprobability carrier, so should not every claim kernel-checked at the exact stratum extend to the general carrier by taking limits? The answer has a shape, and both halves of it are kernel-checked (`SuFunctor.Plain.SeamDensity`).

First, vocabulary: “exact” names finite *support*, not rational *data*. The exact stratum’s weights are arbitrary reals in  $[0, 1]$ ; the data a certificate checker consumes — rational weights, admitting exact arithmetic — is a further sub-stratum. Its density step is kernel-checked: rounding weights down to multiples of  $2^{-n}$  converges narrowly, mass only dropping, so wherever the seam is dense, the dyadic-rational seam is already dense (`Joint.dense_ratSeam`). Density of the seam itself is the classical statement of [192, Thm. II.6.3], and is kernel-checked here over separable pseudometrizable carriers (`Joint.denseRange_toMeas`, `Joint.denseRange_toMeas_of_pseudoMetriizable` — covering the chapter’s Polish standing generality), with the truncation instance over  $\mathbb{N}$  proved by an independent second route (`Joint.denseRange_toMeas_nat`); the transport package is stated against an explicit density hypothesis, so each transport theorem applies at exactly the carriers where density is on record.

Second, the completion itself is one-sided, and the direction is forced by the universe’s own membership hypothesis. Lower semicontinuity makes sublevel conditions closed, and closed sets absorb dense subsets; so *upper* bounds transport — a lower semicontinuous belief bounded on the seam by an upper semicontinuous one is so bounded everywhere (`MeasPen.le_of_seam_le`) — suprema are seam-determined (`MeasPen.iSup_seam_eq`), and narrowly continuous beliefs agreeing on the seam agree everywhere (`MeasPen.eq_of_seam_eq`). *Lower* bounds and infima do not transport, and the failure is semantic rather than a mechanization debt, witnessed at a carrier where density holds: the drop wall — zero at the geometric joint over  $\mathbb{N}$ , infinite elsewhere — is lower semicontinuous (its one proper sublevel set is a closed singleton), sits at infinity on the entire seam, and has infimum zero on the carrier (`dense_seam_inf_gap`). A wall may open exactly at an infinitely supported joint, and no net of finitely supported joints sees it open. So a verdict computed on the exact stratum is exact for suprema and upper bounds and can be unboundedly optimistic for infima and lower bounds; the checker-facing consequence is that safety ceilings certified on rational data complete to the full carrier, while worst-case floors need either upper semicontinuity or the general carrier itself.

What remains constitutively exact-stratum is computation, not semantics: exact rational comparison and decidability are finite-data notions, which is why the checker face lives there — and at finite outcome carriers even the carriers coincide, the seam embedding being a bijection (`toMeas_surjective`).

**The presheaf of classes, and the fork.** The canonical window-restriction of a *class* is the preimage under extension: a spec class  $\Phi_W$  over  $W$  restricts to the subwindow demands it certifies,  $\Phi_V = \text{penExt}^{-1} \Phi_W$  — the presheaf of spec classes over the site. A window-indexed family can then satisfy two disciplines.

**Definition 9.34** (Matching and persistent families). Let  $\Phi = (\Phi_i)_i$  be a window-indexed family of spec classes over a window system  $U$ , with extension maps  $\text{penExt}_{ij}$  for  $U_i \subseteq U_j$ .

- *Matching families* (strict sections):  $\Phi_i = \text{penExt}_{ij}^{-1} \Phi_j$  for every  $U_i \subseteq U_j$  (`SuFunctor.Site.IsMatching`)
- *Persistent families* (lax sections): extension carries each window's members into every superwindow's class,  $\text{penExt}_{ij}[\Phi_i] \subseteq \Phi_j$  (`SuFunctor.Site.IsPersistent`)

The fork between the two disciplines is settled by a theorem, and it is the one place the site dimension exerts force on the composition calculus:

**Theorem 9.35** (The matching fork). *Matching families are not closed under the window-wise composition of decorations: there exist matching families  $\Phi, \Psi$  over a two-window system whose componentwise composite (the window compositor of Definition 9.44, applied per window) is not matching. Persistent families are closed under every operation of the decoration calculus — tight transport, cell transport, composition, and the unit.*

The witness is small enough to describe: over a stage line with one extra time point, take the two *support walls* through the shared middle boundary — one demanding the extra point read true, the other false. Each wall generates a matching family; their composite at the superwindow is the zero-support wall (the demands contradict through the shared middle), which is clip-invariant — so the composite's subwindow component, being empty, fails the matching equation against it. Composition manufactures window-local content (here: infeasibility) that strict sections cannot carry (kernel-checked, with the witness exactly as described: `SuFunctor.Site.MatchingFork.matching_not_closed_under_compositor`, against the closure theorem `IsPersistent.image2_boxplusW`). The fibre objects of the construction are therefore the *persistent families* — the lax sections, equivalently the families closed under reading-small-demands-large, the least-committal completion of window-local spec data. The pattern recurs across this universe's gluing theory: record carriers glue exactly (the carrier sheaf, at its stated hypotheses), assessments complete least-committally (the natural extension, adjoint to restriction), and here admissibility itself completes least-committally — in each case the naive expectation locates laxity in the composition operation, and in each case the operations stay exact while the completion happens one construction over. (The gluing clause of that pattern carries the carrier proposition's own hypotheses — directed interior covers, fixed fibre — and the adjunction runs with the natural extension on the left: least among the coherent globals whose restrictions dominate the assessment, at the universal property's stated scope.)

**Class descent, and ideal points as global members.** Over a directed open cover, the descent homeomorphism of Theorem 9.9 induces an order-isomorphism of class fibres,

$$\text{Set}(\mathbb{H}(W)) \cong \text{Set}\left(\varprojlim_i \mathbb{H}(W_i)\right),$$

carrying constructible classes to constructible classes in both directions — the site's fibre stratum and the glued fibre stratum have the same constructible layer (kernel-checked: `SuFunctor.Site.classDescent`, `isConstructibleUnion_classDescent_iff`, with the transport lemmas `IsLocallyClosed.classExt` and `IsConstructibleUnion.classExt` for the free contravariant direction). And the ideal points of the fibre sheaf are exactly the global members: compatible singleton-sections of the point presheaf — per window the clip of one body, compatible by the clip calculus — biject with closed members of the glued ambient (`SuFunctor.Site.bijective_toProjLim`, the descent homeomorphism's underlying bijection consumed whole). A System over the glued window is its compatible family of window bodies — on the nonempty-body stratum the compiled-System scope of section 9.5 draws — and membership in a persistent family is window-local along pullback (`clip_mem_classExt_iff`).

*Remark 9.36* (The full fibre column, and the localic reading). Assembled, the fibre over a window is a four-storey tower, each storey kernel-checked at the strata named in its own section: the *record locus* (closed subsheaf of the Fell carrier at the classical stratum, section 9.4); *laws* over it (the subprobability stratum of section 9.5, pinned by the countable rational determination of Theorem 9.12); the *hyperspace* of denotation bodies; and the *constructible classes* of section 9.7 — crescents in cover-modality shape, closed under the connectives, ordered by inclusion, with membership and inclusion decided by the blocking criterion. The design-normative reading of every storey above the  $\omega$ -semialgebraic state spaces is pointfree — the record storey as the Vietoris powerlocale of the compactified ambient object (the carrier section's own localic reading), the law storey as the valuation locale of the record locale, the hyperspace storey as its Vietoris

powerlocale, each presented by generators and relations (the cover-modality presentation of [233]) so that the whole column externalizes objectwise over the site by geometricity.

That reading is no longer unmechanized design. The point-free library carries a kernel-checked tier of its own, stated on frames — no points, no countability, no  $\sigma$ -algebra. Checked there: the *presented hyperspace frame* — the free frame on hit-and-miss data, quotiented by the least nucleus forcing the transposed hit-and-miss laws — with the Choquet–Matheron determination on its  $\nabla$ -generators, so that the classical theory is recognized as having been pointfree all along, now as a kernel theorem at the localic stratum (Remark 9.13); the *valuation layer* of the law storey, frame-general — valuations with modularity load-bearing, pushforward functorial and the Dirac unit natural (the presheaf structure the storey needs), the dagger promotion chart driven by modularity alone, and the narrow topology *forced*, not chosen: it is the lower topology of the promoted carrier pulled back along the chart (Pointfree.Valuation.Basic, .Promotion, .Topology, .Functor); and the *two-tier tie* — restriction of Borel measures to opens is Scott-continuous exactly on the  $\tau$ -additive stratum (Fremlin’s 414O supplies that stratum under second countability; the Dieudonné measure fences it), continuous from the weak into the narrow topology by the portmanteau open half, natural in pushforward, with the measure-level dagger chart a homeomorphism carrying Prokhorov compactness to the subprobability carrier, the escape phenomenon witnessed without points (a free-ultrafilter valuation refusing Scott continuity against a directed family of opens), and  $\tau$ -additivity re-read as order-continuity into the measure algebra (.Bridge, .BridgeContinuity, .BridgeFunctor, .EscapeWitness, Pointfree.Measure.DaggerChart, Pointfree.MeasureAlgebra.Basic).

What remains argued design is the column reading itself: the identification of each presented frame with the powerlocale of the storey below it (equivalently, that spatialization returns the classical Fell hyperspace — the determination theorem is proven at arbitrary relation sets exactly so that nothing kernel-checked gates on this identification); the geometricity by which the column externalizes over the site; and the prevision-side completion — every Scott-continuous superlinear prevision the lower envelope of its body of subprobability valuations, the double-powerspace reading of [97] — of which the kernel now holds the sublevel-presented gambles, the Choquet pairing, closure of the superlinear class under lower envelopes, and the cheap half (every prevision below the envelope of its body; Pointfree.Prevision.Basic), the representation converse cited.

The boundary, stated exactly: part of the mechanized tier now *is* the localic reading — the determination theorem consumes the presented frame, and the valuation layer is stated on arbitrary frames outright — while the spine this chapter’s sections consume stays deliberately point-set, exact on compact windows, where continuous valuations and Radon measures agree, and the two tiers exchange theorems through the kernel-checked bridge rather than by analogy. Everything classical is stated so as not to obstruct the localic reading; the localic reading now answers with theorems of its own.

## 9.9 Composition: the Double Grothendieck Construction

Chapter 13 catalogues the composition patterns a modeller wields — fusion, pools, dispatch, delayed trace. This section is the stratum underneath: the single categorical construction in which any wiring of open Systems composes, lawfully, so that pattern-level soundness claims have one place to discharge. The route is direct: span-valued lax double functors on the interfaces-and-wirings base, consumed by the double Grothendieck construction at its fully mechanized stratum, with every obligation — the functors’, the totals’, and the projections’ — kernel-checked. Two functors share the base and the machinery, in a division of labour stated where each is defined: the *Spec* functor carries arbitrary classes and the site dimension (the window-indexed persistent families of section 9.8 — the fibre of Specs); the *coupled-DNF* functor carries the constructible presentations of section 9.7 as fibre data, refines the Spec functor along a kernel-checked comparison cell, and its total is the development’s authoritative SingleSiteSemanticUniverse — the double category of System Specs, whose site-indexed culmination, the chapter’s headline object, is stated whole in section 9.10. Two boundaries of that opening are doing work. The operation is total on composable pairs; the conditions that live deliberately *outside* the functor — causality, simultaneity discipline, Zeno exclusion — are side-condition oracles recomputed on each composite, because they could not be object-level: two individually causal couplings can close an algebraic loop, so composition does not preserve them. And the fibres are *Specs*, not System entities: a System enters the total through its denotation, as an ideal point of a fibre, and the entity-level stratum (simulation witnesses as fibre morphisms, refinement as a fibred structure over this one) is a design layer above the total, recorded in the ledger, not part of it. Figure 9.4

Figure 9.4: The two storeys of the composition construction. On the floor lies the wiring base: interfaces  $I, J$ , wire maps  $f, g$  (tight), wiring patterns  $M, N$  (loose, slashed), and a pattern cell  $\gamma$ ; tight morphisms compose strictly, loose arrows up to the invertible structure cells. Hovering above the arrow  $M$  sits its fibre, drawn upward in the plane the dashed verticals span: each storey is  $M$  again, now carrying a decoration, and height orders the decorations by how much they assert. A System  $S$  enters at the top, as the singleton  $\{[S]\}$  of its own denotation — its ideal point, the sharpest decoration  $S$  satisfies; a Spec  $\varphi$  enters as the class  $[\varphi]$  it denotes over the wiring; the bottom storey  $\top$  admits every belief and demands nothing. The judgment  $S \models \varphi$  of this chapter’s opening, unfolded to  $[S] \in [\varphi]$ , appears as the globular cell between the top two storeys: an inclusion of decorations over a fixed pattern is a cell of the kernel-checked judgment layer (`SuFunctor.QtslSem.SpecJudg: SpecJudgLayer, cell0fSubset`), and the layer is thin, so the cell carries no data beyond the judgment it witnesses. The tower descends from sharp to weak: every class includes into  $\top$ , so  $S \models \top$  comes for free as the composite cell, and  $S \models \varphi$  is the storey that costs something. Judgment cells also compose loosewise, along the wiring: an initial condition enters as one more decorated arrow and conjoins through the compositor, which is monotone (`wComp_mono`), while an undemanded face costs nothing (`wUnit_transparent`); this is how component judgments assemble the composite judgment at the composite wiring. Stripping the decorations lands every storey on  $M$  and every cell shown upstairs on the identity cell of  $M$ . The total of Theorem 9.46 refines this picture: its objects fix a designated Spec at each interface, and its strict projection to the floor lifts uniquely — a discrete double opfibration. The designations at the objects are chaining contracts, matched on the nose when wirings compose; entailment lives upstairs, in the fibre order, as drawn.

draws the destination: the wiring base on the floor, and above one wiring its fibre of decorations, where a System’s ideal point, a Spec’s class, and the judgment between them all live.

The ambient notions come first, at reference width — this chapter is the book’s authority for them.

### 9.9.1 The Ambient Notions

**Definition 9.37** (Pseudo double category). A *pseudo double category*  $\mathbb{D}$  consists of: a category  $\mathbb{D}_0$  of *objects* and *tight morphisms*; for each pair of objects, a collection of *loose arrows*  $m: X \rightharpoonup Y$ ; for all loose arrows  $m: X \rightharpoonup Y, n: X' \rightharpoonup Y'$  and tight morphisms  $f: X \rightarrow X', g: Y \rightarrow Y'$ , a collection of *cells*  $\alpha: m \rightarrow n$  over  $(f, g)$ ; tight-wise identity cells and tight-wise composition of cells; loose identities  $\text{id}_X: X \rightharpoonup X$  and loose composition  $m \odot n$ , with loose-identity cells on tight morphisms and loose-wise composition of cells; and invertible globular structure cells — associators  $a_{m,n,p}: (m \odot n) \odot p \rightarrow m \odot (n \odot p)$  and unitors  $\lambda_m, \rho_m$  — subject to: the tight-wise category laws (loose arrows and cells form a category  $\mathbb{D}_1$  whose source and target functors land in  $\mathbb{D}_0$ ); functoriality of the loose identity and of loose composition with respect to tight-wise composition (the interchange law); tight-wise naturality and invertibility of the structure cells; and the pentagon and triangle laws. Equations between cells whose tight boundaries agree only up to the category laws of  $\mathbb{D}_0$  are read modulo the canonical transport of cells along those laws. The notion is

Grandis and Paré’s weak double category [100, 101]; the tight/loose terminology follows Shulman [219]. When the structure cells are identities,  $\mathbb{D}$  is a strict double category.

*Remark 9.38* (Mechanization of the ambient notions). Kernel-checked, in the double-category library of the proof-artefact repository: the data and the eighteen axiom clauses as `PseudoDoubleCategoryStruct` and `PseudoDoubleCategory` in module `DoubleCat.Basic` — cells dependently indexed by their tight boundaries, with the boundary identifications this definition reads silently carried by an explicit transport operator (`Cell.cast`), and every axiom whose two sides have propositionally-but-not-syntactically equal boundaries stated up to that transport. Lax double functors (Definition 9.39) are `LaxDoubleFunctor` in `DoubleCat.Functor.Lax`, with pseudo-ness as an invertibility property. The library further carries, at the same kernel grade: tight and loose transformations and modifications, assembling the functor double category; the loose bicategory bridge, through which the library inherits bicategorical coherence rather than re-proving it; companions, conjoints, and equipments, with spans the first genuine equipment (and a proof that the double category of commutative squares is not one); and the span and matrix models, including the dependent-span model (`DoubleCat.DepSpan`) on which the Grothendieck construction below is stated.

**Definition 9.39** (Lax double functor). Let  $\mathbb{A}$  and  $\mathbb{B}$  be pseudo double categories. A *lax double functor*  $F: \mathbb{A} \rightarrow \mathbb{B}$  consists of a functor  $\mathbb{A}_0 \rightarrow \mathbb{B}_0$  on objects and tight morphisms; an action on loose arrows ( $m: X \multimap Y$  to  $Fm: FX \multimap FY$ ) and on cells (preserving tight boundaries strictly, functorially for tight-wise composition); a *compositor* family of globular cells  $Fm \odot Fn \rightarrow F(m \odot n)$ ; and a *unit comparison* family  $\text{id}_{FX} \rightarrow F(\text{id}_X)$  — subject to naturality of both families in cells and tight morphisms respectively, associativity coherence of the compositor against the associators, and the two unit-triangle coherences against the unitors.  $F$  is *pseudo* when compositor and unit comparison are invertible, and *strict* when they are identities.

## 9.9.2 The Wiring Base

The base of the construction is the interfaces-and-wirings layer, itself kernel-checked, in a presentation chosen so that the transport identities a decoration tier consumes hold definitionally. The semantic description first, then the presentation.

**Definition 9.40** (Wire types, interfaces, and state spaces). Fix a set  $\mathbb{T}$  of *wire types*, and for each  $t \in \mathbb{T}$  a nonempty Polish space  $\text{El}(t)$  of states of that type, per the standing structure of Definition 9.15. An *interface* is a finite set of wires typed over  $\mathbb{T}$ ; interfaces and type-preserving maps form the slice category  $\text{Wire} = \text{FinSet}/\mathbb{T}$ , which has all finite colimits, computed as in `FinSet` with the induced typing — any two wires ever identified by a zigzag of type-preserving maps have equal types, so quotients are type-coherent automatically. A *wiring pattern* from  $I$  to  $J$  is a cospan  $I \rightarrow A \leftarrow J$  in `Wire`; its legs may be non-injective, which is how a pattern identifies wires — all identification of wires lives in the legs (equivalently, in the quotient forming the apex), never in the tight direction. Patterns compose by pushout of apexes.

The paradigm pattern is a plugging: to wire a controller’s output into a plant’s input, take the cospan whose apex is the quotient of the disjoint union identifying exactly those two wires. The legs stay injective — the identification lives in the apex — and composing two pluggings by pushout chains them through the shared middle interface.

**Definition 9.41** (State spaces, joints, and marginalization). For an interface  $I$ , the *state space* is the product  $\mathcal{X}(I) := \prod_{x \in |I|} \text{El}(\tau_I(x))$  of its wires’ state spaces — a Polish space, finite discrete when every type is finite. A type-preserving map  $\varphi: I \rightarrow J$  induces the continuous *restriction*  $\varphi^*: \mathcal{X}(J) \rightarrow \mathcal{X}(I)$ , contravariantly functorial, and  $\mathcal{X}(-)$  carries the finite colimits of `Wire` to limits: restriction along a pattern’s pushout legs is a homeomorphism  $\mathcal{X}(A+_JB) \cong \mathcal{X}(A) \times_{\mathcal{X}(J)} \mathcal{X}(B)$  onto the agreement subspace. *Joints* over  $I$  are elements of  $\Delta_{\leq 1}(\mathcal{X}(I))$  — subprobability laws, read per section 9.5 as probability joints over the cemetery-completed carriers, so that partiality composes along the cemetery coordinate; the *marginalization* induced by  $\varphi$  is the pushforward  $\varphi_{\#} := (\varphi^*)_*: \Delta_{\leq 1}(\mathcal{X}(J)) \rightarrow \Delta_{\leq 1}(\mathcal{X}(I))$ , functorial and weakly continuous — the functor part of the Giry monad [95], and that sentence is kernel-checked verbatim at this generality: pushforward of subprobability Borel joints is total, functorial along measurable maps — measurability binding exactly at functoriality, the stratum’s constitutive fact — mass-exact, weakly continuous along continuous maps, and literally `Measure.map` under the coercion (`SuFunctor.Plain.MeasJoint`: `push_id`, `push_push`, `mass_push`,

continuous\_push, push\_toMeasure). When  $\varphi$  is a coprojection,  $\varphi_{\#}$  is marginalization of a joint onto a factor, which is the sense in which every  $\varphi_{\#}$  below is read.

*Remark 9.42* (Two strata: Polish semantics, exact-rational certificates). Stated once, here, for the whole composition tier. The *semantic* stratum — every definition of this section — lives at the standing generality of Definition 9.15: Polish record spaces carrying the weak topology on their subprobability measures (the vague topology’s role, and why the weak one is the topology of record, are settled there), with the Borel  $\sigma$ -algebra underneath. Finiteness, where it genuinely binds in a theorem, enters as a hypothesis, never as a regime of the space. The *certificate* stratum is exact-rational certification over the locally closed  $\omega$ -semialgebraic carriers of section 9.2, and what is finite there is the *presentation*, not necessarily the space: in dimension zero distributions are rational mass tables and sublevel checks are linear programs; in positive dimension the finite object is a vector of rational polynomial coefficients per piece, countable piecing is expressed by functorial plates at the hypernet stratum — one finite object denoting a whole shape-indexed family, naturally in the index — and discharged shape-uniformly at the certificate stratum through pooled aggregate coordinates, so that a certificate discharges polynomial inequalities over an uncountable carrier without enumerating it; count-budget rows survive as optional tightenings, not as the price of admission, and the standing convention below keeps the non-uniform residue. What connects the strata is the standing convention: data outside the exact fragment — non-semialgebraic carriers, non-polynomial scores (the logarithms constituting relative-entropy beliefs included) — ride the wire through outward rational bounds, which enlarge the credal body, the sound direction.

*Remark 9.43* (Hiding a wire: inf-projection, the reflector, and the tightness certificate). The composition calculus marginalizes *joints*, never beliefs (the compositor below); but the assembled stack does eventually hide wires — a demand read over visible coordinates with the hidden ones existentially absorbed — and the semantic content of hiding is the inf-projection of a belief along the pushforward. Its status at the standing generality is fixed by three kernel-checked facts (SuFunctor.Universe.Marginalization). First, the boundary is real: inf-projection does not preserve lower semicontinuity — the witness is escaping mass along the hidden coordinate, a closed family of near-unit point masses whose image under the visible marginal is not closed (exists\_lowerSemicontinuous\_not\_lowerSemicontinuous\_infProj) — so the naive hidden-wire denotation can exit the universe. Second, the repair is judgment-invisible: hiding taken as the lower-semicontinuous envelope of the inf-projection changes no judgment against any citizen of the universe — the envelope is a reflector, and domination against a hidden-wire system never evaluates the infimum at all, resolving upstairs as ordinary domination through the inf-pullback adjunction (le\_lscEnv\_iff, le\_hide\_iff, le\_infProj\_iff) — and the relaxation only lowers the system side, the sound direction. Third, a certificate turns the naive formula exact: for beliefs whose sublevels are tight — equivalently compact, the Prokhorov reading, mechanized as consumption (isCompact\_sublevel\_of\_isTightMeasureSet) — sublevels of the inf-projection are *exactly* the pushforward images of sublevels, the infimum is attained wherever finite, and the inf-compact class is closed under marginalization (sublevel\_infProj\_eq, exists\_infProj\_attained, isCompact\_sublevel\_infProj, lowerSemicontinuous\_infProj, with the coordinate instantiation sublevel\_infProj\_margFst\_eq). The calculus’s generator- and moment-row certificate species are, read at this stratum, inf-compactness certificates; and one coercive summand puts a whole additive composite in the class — a one-line consequence of nonnegativity, the composite’s sublevels sitting closed inside the summand’s compact ones — so tightness enters as a certificate on the operand that needs it, never as an axiom of the universe.

**The mechanized presentation of the base.** The kernel-checked form of the wiring base presents patterns by their *state families*: the base double category has as objects interfaces (bundles of wires over a fixed state type — the untyped stratum, the typed slice being orthogonal bookkeeping), as tight morphisms wire maps acting on states by restriction, as loose arrows patterns presented as type-valued families  $M: \mathcal{X}(A) \rightarrow \mathcal{X}(B) \rightarrow \text{Type}$  — for a cospan, the family of apex states restricting to the given boundary states — with apex state space the total  $\text{Tot } M = \sum_{x,y} M(x,y)$ , loose composition the  $\Sigma$ -pullback (exactly the agreement subspace of Definition 9.41), and cells acting on apex states backward (a map of patterns pushes apex wires forward, hence pulls apex states back over the boundary restrictions). In this presentation the wire category’s laws are definitional, every boundary transport vanishes, and the comparison identities of iterated pullbacks — the entire calculus a decoration tier consumes — hold by reflexivity (kernel-checked: DoubleCat.WireSpan, a full PseudoDoubleCategory instance; the associativity-transport identity of the total-state calculus depends on no axioms at all). Variable identification stays out of the tight direction by construction: tight morphisms act on states by restriction and never quotient anything, and

all identification lives in the pattern families.

### 9.9.3 The Decoration Functor

**Definition 9.44** (The decoration functor: Specs over the wiring base). Fix a stage type with a window system  $U$  (the site dimension, entering through the decoration per [section 9.8](#)) and a state type. The *decoration functor* assigns:

- to each interface  $A$ , the *fibre of Specs*: persistent window-indexed families of classes of beliefs on joints over trajectories in  $A$ 's state space, ordered componentwise by inclusion — such a family is precisely what a Spec denotes, and the fibre is named accordingly;
- to each tight morphism (wire map), the componentwise image of belief transport along the induced trajectory restriction — covariant on classes, because states restrict contravariantly;
- to each pattern  $M$ , the decorations: persistent window-indexed families of classes of beliefs on joints over apex trajectories ( $\text{Traj}(W, \text{Tot } M)$ ), with boundary parties supplied by the indexing;
- to each cell, the componentwise image of belief transport along the backward apex-state map;
- as compositor — the *belief laxator*  $\boxplus$ , the name later chapters use for this operator — the componentwise elementwise *pushforward-then-add*: for decorations  $\mathcal{U}$  over  $M$  and  $\mathcal{V}$  over  $N$ ,

$$\mathcal{U} \boxplus \mathcal{V} := \left( \left\{ (\pi_M)_\# \circ u + (\pi_N)_\# \circ v \mid u \in \mathcal{U}_W, v \in \mathcal{V}_W \right\} \right)_W,$$

where  $\pi_M, \pi_N$  are the joint-to-component projections of the glued apex: the joint over the composite is marginalized to each component's trajectory space, each component belief is precomposed with its marginal map, and the results are added in  $[0, \infty]$  — the beliefs are never themselves marginalized; the joint is;

- as unit, the componentwise singleton of the vacuous belief (zero everywhere) on identity-pattern trajectories — the *austere* unit: everything permitted, no residue.

These data satisfy every obligation of a span-valued lax double functor on the wiring base — functoriality of both transports, naturality of compositor and unit, associativity and both unit coherences — and persistence of every result is the site-direction naturality package (extension commutes with state-side transport, with the window compositor, and fixes the unit).

*Remark 9.45* (Mechanization status of the decoration functor). Kernel-checked, end to end, at three strata of the semantic-universe strand — two nested, one general. The single-window (plain) stratum: carriers and transports in `SuFunctor.Plain.Penalty` (Joint — finitely supported subprobability joints over an arbitrary carrier, partiality native —, `Pen`, `Pen.pull`), the functor with all obligations in `SuFunctor.Plain.SpecFunctor`, its acceptance battery in `SuFunctor.Plain.Battery`. The site-indexed stratum, which is the carrier of the construction's site dimension: window carriers and the extension calculus in `SuFunctor.Site.WindowPenalty` — at both joint strata: the same calculus over subprobability Borel joints, with its persistence closure package and the seam theorems, is `SuFunctor.Site.GeneralWindow` ([Remark 9.33](#)); both are stated over the function presentation of the trajectory carriers — graphs before closure, per [section 9.8](#) — with the Fell-carrier restatement the closing ledger's obligation —, the functor `siteSpecFunctor` with all obligations proved componentwise in `SuFunctor.Site.SiteFunctor`, the battery in `SuFunctor.Site.Battery`, and the matching fork in `SuFunctor.Site.MatchingFork`. The componentwise reduction is itself the structural finding: the seven obligations never see the site — each reduces, window by window, to the single-window coherence core, because trajectory transport is definitionally functorial and the base's transport calculus is reflexivity-valued — so the site dimension's entire force lands in fibre admissibility ([Theorem 9.35](#)), never in the functor laws. The *general* stratum carries the same single-window calculus over subprobability Borel joints on arbitrary measurable carriers: the scalar stock whole — pushforward, belief transport, the compositor over arbitrary marginalization pairs, weak continuity, the lower-semicontinuity closure package with wall-grade attainment on nonempty compacts, and the compactly-supported subclass closed under transport (`SuFunctor.Plain.MeasJoint`) — the coherence *cores* base-free, with the wiring base's comparison identities carried as commuting-square hypotheses (the finite tier's cores are the all-squares-by-reflexivity special case); the tight-tier functor over measurable carriers with the acceptance battery transposed row by row, refutation pins included

(`SuFunctor.Plain.GeneralFunctor: measSpecObj`). The residue: the double-categorical *total* at the general stratum is not claimed — the cores consume comparison squares the exact base discharges by reflexivity, and a measurable wiring base carrying its own transport data is the remaining object, a design artefact in its own right, recorded in the ledger.

#### 9.9.4 The Construction

The double Grothendieck construction — in the covariant, span-valued form Patterson [193] used to rebuild decorated cospans [80], the strict-tight face of the double fibrations of Cruttwell, Lambert, Pronk, and Szyld [52], whose discrete case is Lambert’s [149] — at the dependent (span-of-types) stratum, assembles the decoration functor into the *double category of System Specs*: objects are interfaces with a designated Spec; tight morphisms are wire maps with fibre transport; loose arrows are patterns with a decoration; cells are pattern cells with transported decorations; loose composition pairs the base composition with the compositor. Open Systems live in this total as embedded ideal points of its fibres — the paragraphs below — never as a separate object class. The projection to the wiring base strips the decorations, and it is *strict* — its compositor and unit comparison are identities.

**Theorem 9.46** (The assembled total, and its projection). *The total of the decoration functor under the double Grothendieck construction is a pseudo double category, and its projection to the wiring base is a strict double functor that is a discrete double opfibration: tight morphisms out of a fixed source and cells out of a fixed loose arrow both lift uniquely.*

*Remark 9.47* (Mechanization status of the construction). Kernel-checked, and the division of labour is where the proof burden sits: the Grothendieck construction, the pseudo double category instance on the total (all eighteen axioms), the strict projection, and the generic discrete-opfibration theorem are proved once, for an arbitrary span-valued functor on an arbitrary base (`DoubleCat.Grothendieck`, `DoubleCat.Opfibration`; the general split-opfibration development — `opcartesian` lifts, `opcleavages` compatible with source and target, split laws as theorems about the canonical lifts, and the hom-level isomorphism between fiberwise transformations and strictly projection-compatible functors — is kernel-checked at the same stratum, choice-free); the construction then consumes the generic theorems by instantiation (`SuFunctor.Site.SiteSpecTotal`, `siteSpecTotal_pseudoDoubleCategory`, `siteSpecProj_isPseudo`, `siteSpecProj_discreteOpfibration`) — a one-line consumption in each case, because the generic lifting calculus never inspects fibre internals: the window index travels inside the fibre objects, invisible to it. The variance is forced, not chosen: beliefs push forward totally along wire maps, but cannot be pulled back without a lossy infimum — the cartesian (negative) half, preimage-transport lifts assembling the image-preimage adjunction on class fibres, is a named obligation of the ledger. One generality note: span-of-categories generality is consumed nowhere in the construction — the Spec fibres are dependent families of types, exactly the stratum at which every general theorem above is kernel-checked, so no gap opens between the stated and the mechanized generality. The entity-level fibres (fibre *categories* of Systems and simulation witnesses) are the refinement layer above this total — design, recorded in the ledger, with the general machinery it would consume already kernel-checked, and with a prose-verified construction retained in the workshop record as its design basis; the paragraph closing this section says why that layer is expected to be lighter than a second Grothendieck construction.

#### 9.9.5 The Authoritative Total: Presentations as Fibre Data

The class-level construction above carries arbitrary classes; the authoritative total of the spec tier sharpens the fibres to the class stratum’s own normal form, carried as data. The *coupled-DNF decoration functor* assigns to each interface the coupled-DNF presentations over its state space — finite families of spec atoms, each a safety floor with a finite liveness family containing the properness demand (the option-A discipline: the vacuous atom is  $(0, \{\top\})$ , and an empty liveness family is unrepresentable rather than merely forbidden) — and to each wiring pattern the presentations over its apex. Transport is *atom-level*, disjunct by disjunct — pull the floor and each mark, the canonical fibre operation, judgment-invariant along surjections (Remark 9.49). The compositor is atom-level pairing — floors compose by pushforward-then-add, liveness families by pulled union — and the unit is the vacuous atom itself: the austere unit and the properness demand are the *same atom*, which is exactly why the unit laws close on the nose — every transport fixes the properness mark, and every atom’s own marks absorb it. The plain double Grothendieck total of this functor is the development’s `SingleSiteSemanticUniverse`:

objects are interfaces with a designated presentation, loose arrows are patterns with an apex presentation, and the strict projection to the wiring base is a discrete double opfibration by the same one-line consumption of the generic theorem (kernel-checked, module `SuFunctor.SingleSiteSemanticUniverse: dnfSpecFunctor` with the full obligation package, `SingleSiteSemanticUniverse`, `singleSiteUniverseProj`, `singleSiteUniverseProj_isPseudo`, `singleSiteUniverseProj_discreteOpfibration`). The relation to the class-level functor is refinement, never replacement, and it is a theorem: componentwise, on the surjective sub-base, the image-level transport of a presentation's model class is exactly the model class of the atom-level transport cut to the transport's range — the transport structure theorem of Remark 9.49 instantiated at the wiring base (`specMap_modelClass_eq`), the inclusion half being the comparison cell in the inclusion-ordered fibres (`specMap_modelClass_subset`, with its cell-component companions). Away from the surjective stratum the two genuinely part company, and the atom-level operation is the one under which the fibres keep their constructible presentations: at the finite stratum, through the seam of Remark 9.48, every fibre presents a constructible hyperspace class under semicontinuity of the presented data alone (`Universe.SpecDnf.isConstructibleUnion_probRead` — the finiteness that constructibility consumes is carried by the presentation, by construction). Convexity plays no role at this tier: admissibility of a fibre is constructibility of its presented class, and atoms, presentations, and transport are all indifferent to convex structure. One packaging distinction, stated precisely because it is easy to misread as a gap in the mathematics: the window direction of the site dimension is carried, in full, by the Spec functor above (window-indexed persistent families, section 9.8), composition across distinct clocks is likewise built (the cross-clock paragraph below), and the cross-site direction enters the base as profile-indexing (the profiled-base paragraph below); what the presentation-level total instantiates today is its fibres *per carrier*, so the re-instantiation of the coupled-DNF fibres with window-indexed presentation families — a packaging step, not a new composition theory — is an obligation recorded in the ledger (section 9.13).

**Systems in the total: ideal points, and the order as the fibre carriers' order.** A System enters the class-level total as an ideal point of its interface's fibre — the persistent family of singletons of its window denotations, which is a global member by descent (section 9.8) — and the two structural facts that make the embedding harmless are both battery theorems: the embedding is *monoidal* for composition (singleton decorations compose to the singleton of the composite: `singleton_boxplusW`, `transport_singletonW` — ideal points compose to ideal points, so composing Systems and then embedding agrees with embedding and then composing), and membership agrees with singleton inclusion under the componentwise inclusion order the fibre carriers wear (`wIdealPoint_le_iff`, window by window). One boundary transfers with the claim rather than being smoothed over: monoidality is a class-level, safety-face fact — at the coupled membership relation of the presentation fibres, composing two members of a paired atom's class need not produce a member, one component's liveness dip being destroyed by the other's cost already along identity transports (`exists_coupledSat_add_fails`, kept in the tree as the design boundary); the safety face composes unconditionally (`add_comp_safety_le`), and coherence of the atom pairing is a statement about presentations, never about membership of composed models. One precision, so the categorical claim is not stronger than the machinery: that inclusion order is *external* structure on the fibre carriers — the construction's Grothendieck data are dependent families of types, and no order is part of them — so “the order is the fibre order” is shorthand for a statement about the carriers the fibres happen to be, not about the discrete opfibration. The order does, however, carry a kernel-checked double category of its own: the thin *judgment layer* over the same wiring base, whose loose arrows are decorated patterns and whose cells over identity boundaries are furnished by inclusions of decorations (`DoubleCat.JudgLayer`, kernel-checked at the single-window stratum; instantiated at this tier in `SuFunctor.QtslSem.SpecJudg: SpecJudgLayer`, `cellOfSubset`, with thinness as `cell_subsingleton`) — the upstairs plane of Figure 9.4, and the shape in which the judgment  $S \models \varphi$  composes as a cell. The order-enriched refinement of the total itself, in which the designated fibres and the inclusion cells would live in one structure, remains an obligation recorded in the ledger. With that precision, the one-universe thesis acquires its structural form at the present grade: one fibration over the wiring base, Specs as fibre objects, Systems as ideal points inside those fibres, the universe's order read off the fibre carriers, and the base direction reserved for wiring.

### 9.9.6 The Composition Law

The law itself — pushforward-then-add, lifted to classes — carries two theorems, each with its kernel receipts, and their conjunction is the exact statement of what composing stochastic wirings means.

*Coherence (the law is lawful).* Composition of decorations is associative and unital on the nose modulo the base’s transport, with no renormalization anywhere, because no axiom needs one: the unit is austere and composes transparently (`wUnit_transparent`), the composite class is exactly the image of the pairs — nothing is forgotten that a coherence law could detect (`mem_wComp_iff`; nonempty inputs give nonempty composites, `wComp_nonempty`) — and the element-level coherence calculus reduces through the pushforward calculus to the commutative-monoid laws of  $[0, \infty]$ . The battery fixes the design against its named neighbours, as refuting theorems rather than advice: a *taxed* compositor (any constant surcharge on composites) breaks unit transparency (`taxedBoxplusW_breaks_unit_transparency`); a *funnel* compositor (forgetting the pair content) breaks the unit law against the empty class (`funnelCompW_breaks_unit_coherence`); and composing decorations along mismatched middle interfaces is not wrong but *unrepresentable* — a type error at the total, pinned as a build-time refusal.

*Containment, not identity (the law is more committal than the glue).* Read through the compile isomorphism, the composite belief’s body is contained in the natural-extension glue of the components’ bodies over the shared interface — always, with no topological hypotheses — and the containment is strict off the crisp locus: in grade coordinates the law is the *product* triangular norm while the glue is the *minimum*, and

$$\pi_1 \circ f_1 + \pi_2 \circ f_2 = \max(\pi_1 \circ f_1, \pi_2 \circ f_2) + \min(\pi_1 \circ f_1, \pi_2 \circ f_2),$$

so the two sides agree at a joint precisely when the joint is crisp — one side at 0, or one side at  $\infty$  (per the identity’s reading in [section 9.5](#): the min-term is not a cancellative gap at infinite heights) — and the crisp locus, where every joint is crisp, is exactly the equality locus. There deterministic intuition is exactly right that composition is conjunction: on indicator beliefs both compute intersection of behaviours. Off the crisp locus a compact exact-rational counterexample closes the question permanently: two single-edge dependency-graph models disagreeing about a shared binary variable (relative-entropy beliefs toward  $(\frac{2}{3}, \frac{1}{3})$  and  $(\frac{1}{3}, \frac{2}{3})$ ) admit the witness  $\frac{9}{10} \cdot \text{uniform}$  inside the glue but outside the composite — the two decisive comparisons being  $81 > 80$  for exclusion and  $729 \leq 800$  for inclusion — and both sides are already compact, convex, and scaling-closed, so no closure rescues equality. Containment theorem, crisp-locus characterization, and strict witness are kernel-checked in this repository at both strata: at the finite stratum (module `QtslAux.Imprecise.Containment`; the irrational glue grade enters through the square dictionary and an exact rational split, and the two decisive comparisons are hand-checkable arithmetic), and at the general stratum (module `QtslAux.Imprecise.ContainmentGeneral`) — the containment over arbitrary carriers, an order-pure argument consuming no tightness anywhere (`sublevel_compositeG_subset_glueSetG`, `certificate_transfer`), instantiated at pushforwards of laws with the glue closed (`sublevel_pmComposite_subset_glue`, `isClosed_pmGlueSet`), the crisp locus characterized exactly at the denotation level (`forall_sublevel_eq_iff`, through the exact-scale identity `ENNRat.add_eq_max_iff`: a sum equals the join precisely when the lesser term vanishes or the greater is infinite), and strictness witnessed on a compact carrier, the finite counterexample above entering as the loaded instance — finite discrete carriers are already of the standing generality (`binaryComposite_ne_glue`, `sublevel_ssubset_glue_witness`). The direction of the containment is the sound one — certificates bound every element of the glue, hence a fortiori the composite — and the gap is conservatism, never unsoundness; by the wall-blindness lemma of [section 9.12](#), no wall-fragment verdict can even observe it, so the conservatism costs only the graded successor, and there per-slice.

**Inconsistency and feasibility.** Because beliefs add, two wirings can compose to the everywhere-infinite belief — which compiles not to the empty set but to the bottom credal body, a lawful decoration: composing contradictory constraints *should* denote infeasibility, and it does so first-class, with the boundary verdicts of [section 9.7](#) adjudicating which classes an infeasible composite inhabits — every safety containment, no liveness escape, hence no presented atom’s class (Remark 9.16 and Remark 9.31). Properness of a composite has an existential characterization with a constructive witness: the composite belief is proper iff some pair of component joints, each of finite inconsistency, agrees over the shared interface, and a compatible pair yields a witnessing joint by exact conditional-product gluing — a characterization, not a decision procedure: what the theorem supplies is the shape of the check and the witness format. The coupling ingredient — two laws with equal pushforwards over the shared interface admit a coupling concentrated on agreement, at standard-Borel strength — is kernel-checked in this repository (`QtslAux.Imprecise.CouplingGlue`); the packaged equivalence at both strata, with the finite conditional product as an exact rational formula, is kernel-checked beside it (`QtslAux.Imprecise.FeasibilityGlue`). Soundness of the additive law needed no check at all — every joint the composite admits has its component marginals inside the components’

certified credal sets, a one-line theorem (the dropped summands are nonnegative) — and the kernel carries the two near-misses that guard it: signed scores break it, and sub-unit confidence weights break it, each falling exactly on a field the wire format retains (nonnegative codomain; unit weights or the rebated conclusion; `signed_relaxation_fails`, `subunit_weight_fails`). The algebraic lemma is checked twice over, on the exact stratum and space-free (arbitrary joint models, finiteness surviving only in the contributor index — arity, not state; the two marginal-compatibility modules above).

*Remark 9.48* (The seam between the two mechanized stocks). The composition tier’s exact stratum (finitely supported subprobability joints over arbitrary carriers) and the judgment tier’s finite stratum (laws as real weight functions over a finite outcome type) are two presentations of one object, and the identification is kernel-checked rather than asserted: an equivalence between the two carriers respecting mass, zero, and the probability slice, an order isomorphism of the belief stocks by precomposition, and the judgment bridge — the fibre-order membership judgment of the total transported onto the judgment tier’s belief type, where the crescent machinery of [section 9.7](#) consumes it (`SuFunctor.Plain.Seam: jointEquivBel, jointEquivProb, penEquiv`, and the transported membership `iff`). A second seam runs upward, to the general stratum: the exact joints embed in the subprobability Borel joints as weighted point masses, respecting mass, zero, and pushforward — the restriction theorem: finite pushforward *is* general pushforward read along the embedding — injectively over measurable-singleton carriers, and at the belief and class levels the finite decoration functor is the restriction of the general one along the seam (`SuFunctor.Plain.GeneralSeam: Joint.toMeas, toMeas_push, toMeas_injective, pull_toMeas, image_pull_toMeas`). The three mechanized stocks — weight-function laws at the finite stratum, finitely supported joints at the exact stratum, subprobability Borel joints at the general stratum — thus form a kernel-checked nested ladder, and every statement this chapter makes across stocks factors through these seams.

### 9.9.7 Transport, Clocks, and Profiles

*Remark 9.49* (Constructibility under transport: adjudicated). The construction’s fibre objects are, in the kernel, persistent families of *arbitrary* classes of window beliefs; the stratum of [section 9.7](#) distinguishes the constructible classes inside them, and whether the construction’s operations keep the semantics on the constructible stratum is now adjudicated rather than open, with the answer fixing a design decision (kernel-checked, module `SuFunctor.Universe.TransportCitizenship`). The transport dictionary is the keystone: the body of a transported belief is the *preimage* of its body (`compile_pullPen`), so at the body level transport is preimage — which preserves local closedness and constructibility outright — and the coupled membership relation is transport-invariant along surjections (`coupledSat_pullPen_iff`; off the surjective stratum the invariance fails in both directions — dips can sit outside the range, and safety can be violated there). At the class level the admitted operation is *atom-level* transport — pull the atom’s data, form its crescent — and not image transport of classes: for surjective wire maps the two agree up to an exact structure theorem (the transported crescent is the pulled atom’s crescent intersected with the saturated classes — those equal to the preimage of their image — both inclusions: `transportClass_crescentClass`), while a non-surjective counterexample shows raw image transport escaping the pulled atom’s crescent (escape witnesses die off-range: `exists_transport_not_subset_pulled_crescent`). The compositor has its own dictionary — the body of a sum is the fibrewise radial grade product (`compile_add_radProd`) — and union-distribution receipts close the question against the forcing schema of [section 9.7](#): the atom-level operations distribute over the constructible unions, transport laxity is licensed in the sound direction, and no closure operator re-enters through transport. Class descent preserves constructibility in both directions independently ([section 9.8](#)). The packaging is the authoritative total above: the decoration functor re-instantiated with DNF-presented constructible fibres, atom-level transport and composition built on exactly these element cores, and the comparison cell supplied by the structure theorem; the composite-atom liveness set is carried by the compositor itself (pulled union, properness mark absorbed). Strata, stated plainly: everything this remark names is kernel-checked at the finite stratum (`SuFunctor.Universe.TransportCitizenship`) *and* at the general carrier (`SuFunctor.Universe.General.TransportGeneral`, transports the continuous maps with Borel codomain): the transport dictionary rests on mass exactness and scaling linearity of the pushforward (`compile_pullPen`), the coupled judgment is transport-invariant at surjective *pushforwards* (`coupledSat_pullPen_iff`, with both off-surjective failure directions kernel-checked rather than parenthetical), and the structure theorem splits where its hypotheses genuinely bind — the forward inclusion under surjectivity, the reverse under a named image-closedness supply (the price compactness paid silently at the finite stratum), equality under a closed map. Two hypotheses earn their own mention: bare surjectivity

of a wire map does not yield a surjective pushforward at the general carrier (a measurable-selection matter; a measurable section suffices, kernel-checked as `probPush_surjective_of_section`), and ideal-point constructibility wants a  $T_1$  hyperspace, available over locally compact ambients. Two residues remain, recorded in the ledger — closedness of the saturation locus (which would upgrade image transport itself to an admitted class operation on the surjective stratum) and constructibility of non-surjective images.

**Composition across clocks.** Heterogeneous-time composition — a discrete-time controller against a continuous-time plant, distinct clocks per wire — enters the construction as content of the decoration, not as new machinery; three facts make the seam tractable, the first two kernel-checked, the third proven in adversarially reviewed prose in the development’s workshop record. First, a declared clock morphism (nominal rate with a jitter band, and its hold) enters the composite’s belief content as one *wall on the joint record space* — the indicator of the admissible co-realizations, one shared realization per clock instance — and spec-to-spec reasoning across the seam is decided by the same blocking criterion as within one site, with the sampler’s wall joined into the premise floor as one more conjunct: exact at both the membership and the class level, kernel-checked (`SuFunctor.Universe.DemonicClock: cross_site_union_refinement_iff` — the criterion on the joint floor — with the lower-semicontinuity supply that keeps the adversary class closed, `lowerSemicontinuous_selSup`; criterion and supply are carrier-general, and the wall species with the class-level exactness are kernel-checked at the general carrier too (`SuFunctor.Universe.General.DemonicGeneral: probWall` with its citizenship characterization, `crescentClass_inter_wall`, `cross_site_union_refinement_iff_probWall`), so the sentence holds at every stratum; the sampler-relation stock and its exact composition laws, with prevision transport and certificate soundness across the seam, in `DoubleCat.CrossSite`). Second, transporting behaviour across a relational (jittered) seam is a genuine functor once it acts on *bodies* — all realizations at once, no choice — with composition preserved on the nose: the record-tier no-go (a functional transport would have to choose realizations; kernel-checked as `exists_no_functional_transport`) is evaded one storey up, where the Egli–Milner lift of closed relations composes exactly, the middle witness being an intersection rather than a selection (`SuFunctor.Universe.DemonicClock: emLift_comp`, axiom-free, following the endofunctor theorem of Abbadini, Bezhanishvili, and Carai [7]; what that theorem’s non-allegory caveat actually marks is *meets* — the lift of an intersection of relations can be strictly below the intersection of the lifts, kernel-checked as a one-bit fixture). Third — the prose-proven fact — everything genuinely lossy in crossing a seam is one mechanism in three costumes: an envelope or meet taken *before* a transport forgets shared-realization correlation. The sound discipline is uniform: conjoin walls and compose relations first, envelope once, last. The remaining laxity of the cross-site glue is thereby located, not diffuse, with its species named: the per-component exchange between coarsening and marginalization is *exact* for the pushforward of a single law (naturality, consuming continuity only — no measurability clause anywhere in the proof, records transporting by the carrier’s clip-and-push legs); at the credal species the same exchange is lax in general and strict under a fine-lift (surjectivity) hypothesis on the transports — satisfied by the paradigm coarsenings, where every coarse record is some fine record’s restriction. Under that hypothesis the single inclusion of the coarsening theorem is entirely the glue-gap — direct images under-distribute over meets — and in every case the certified direction is sound. On a pipeline that observes the discipline — and whose exchange satisfies the fine-lift hypothesis — the wall’s width is the seam’s entire price: relation composition is exact, the body-tier lift is exact, the exchange is strict, so what a jittered clock charges is the relaxation of the realization wall itself — wider realization classes, weaker walls, more admitted joints — which the order then treats like any other imprecision. Off the discipline, the ledger’s envelope and meet gaps charge too; the discipline is how one avoids paying them.

**The site in the base: profiles.** The construction is *parametric* over state vocabularies and *indexed* over site-profiles, and the two are one design’s two faces. Parametric: no functor law of the decoration tier inspects the state vocabulary, so instantiating at a clocked vocabulary — realized records carrying their clock — costs no new proof, and the fibres of the indexed object compute to the fibres already built, definitionally (`spacetimeSpecFunctor_fibre_eq` is a `rfl`). Indexed: parametricity alone would leave the site data ambient-in-the-states — a total that *contains* multi-site content while *knowing* nothing of sites — so the site assignment enters as object data of a profiled base (`SuFunctor.Spacetime.Base`): objects carry a wire-to-clock profile, tight morphisms preserve it — along any raw wire map into a profiled interface there is exactly one source profile making it a tight (`profileLiftHom`, `profile_unique_of_hom`): interfaces over sites, as a fibration fact — and states are the fused states the profile constrains. The indexing is by profiles rather than by single sites because it has to be: a mixed-boundary device (`mixedInterface`) has no object over a single-site

base, and the family-of-one-site-totals reading of “indexed” is refuted under jitter by the relational no-go (`exists_no_functional_transport`, the cross-clock paragraph above). The profile-forgetting embedding (`profiledEmbed`) composed with the decoration functor then yields the iterated double Grothendieck total `SemanticUniverse` — Specs over interfaces over site-profiles — whose strict projection is a discrete double opfibration by one line of the generic theorem (`universeProj_discreteOpfibration`): the lifting calculus never inspects fibres, so the site grading costs it nothing. The two faces stay bridged in both directions: each one-site base sits at the constant profile, with tights, states, and patterns corresponding by equivalences on the nose (`constHomEquiv` and companions — per-site conservativity), and cross-site seams enter the *fibres* as wall conjuncts, the preceding paragraph verbatim, inside the indexed object. One comparison direction is genuinely lax and deliberately so: `profiledEmbed`’s compositor is invertible (a constrained middle state is a fused middle with a membership proof, and proofs are irrelevant) but its unit comparison is not — the profiled identity embeds as the fused identity pinned to the profile, a genuine sub-pattern of the fused diagonal — so forgetting the site discipline is a lax operation because the discipline is information. The outer storey is what makes “which site is this wire on” a question the base can answer and the grammar can enforce.

### 9.9.8 The Monoidal, 2-Functorial, and Certificate Layers

**The monoidal and 2-functorial layers.** The juxtaposition tensor on the wiring base, and with it the symmetric monoidal structure of the assembled total, ride a hypothesis package on the decoration functor — fiberwise tensors with coherence data, plus two families of mediating cells against the compositors — whose status this book reports with its receipts and its history, in [section 9.13](#): the package’s axioms are mechanized as named mixins whose satisfaction and refutation are decidable over cyclic-group graded models, the dependency table among them machine-checked, and the package’s original version omitted an independent associator-interchange axiom, witnessed by a finite graded model. The 2-functorial layer — maps of decoration data inducing maps of assembled totals, with an isomorphism of hom-categories onto the strictly projection-compatible functors — is kernel-checked at the construction’s own stratum (the hom-level isomorphism with explicit inverse and both roundtrip laws, choice-free), with its 2-categorical superstructure at prose grade. Neither layer is consumed by anything the earlier sections claim.

**Certificates: fibrewise morphisms, not a second tower.** An earlier design sketched certificates-over-Systems as a second Grothendieck construction over this one, iterated since opfibrations compose. The tower collapses: in inclusion-ordered fibres a certificate is a *fibrewise morphism* — a witnessed inclusion of an ideal point, or of a smaller spec class, into a larger one — and fibrewise morphisms already compose, vertically by transitivity, along tight and cell transport by monotonicity, and horizontally along the compositor by witness-carrying morphisms, so no second certificate storey is needed: the certificate layer is the order-enriched refinement of the total named above (fibre 2-cells as inclusions), not a new fibration. The collapse is sharper than a tidiness claim, in two kernel-checked ways (module `SuFunctor.Universe.CertificateLayer`). First, certificate transport needs no side conditions: the transported coupled judgment factors through the fibrewise infimum (`fibInf`, empty fibres reading  $\top$  — the right Kan extension along the carrier map) at *arbitrary* carrier maps (`coupledSat_comap_iff_fibInf`), so transported model classes are preimages and spec-to-spec transport is unconditionally monotone (`SpecDnf.comap_modelClass_mono`) — the opfibration line above, beliefs pushing forward totally while pulling back only through a lossy infimum, upgraded from variance remark to mechanism: the lossy infimum reappears exactly once, as the reflection every transported judgment factors through, and surjectivity’s entire load rests on ideal points, whose off-range reflection a non-surjective transport rewrites to  $\top$  (`exists_comp_notMem_modelClass_comap`). Second, the iterated tower is not merely unnecessary but unbuildable in plain form: a second-storey certificate functor would owe a *total* composition laxator, and there are component certificates whose composite target holds no certificate at all (`exists_coupledSat_add_fails`) — the fibrewise picture survives precisely because a fibre-hom may fail to exist without breaking any structure; where the con-witness is supplied the composite exists (`coupledSat_comp_add_of_dips`), and on the safety fragment composition is witness-free. A companion witness locates why the fibres are presentations: two presentations of the same model class whose composites with one fixed atom differ (`exists_boxplus_not_semantically_monotone`) — the compositor is monotone in the presentation order (`dnfBoxplus_mono`) but does not descend to semantic classes, so a composite certificate names the disjuncts it composes and carries the composite dip family. The assume-guarantee calculus of Capucci and Myers [37] is the worked instance of this collapse, not of the iterated construction: their Boolean stratum is the

fibrewise-morphism picture verbatim — a certified lens is a base loose arrow together with fibre-morphism data over its source — and their quantitative construction is itself one double Grothendieck over ordered fibres of bundle predicates, never iterated, with slack composition recovered here as the derived hom-action of the compositor rather than postulated as data. The boundary: everything in this paragraph holds per site-fibre; the site dimension — Specs over interfaces over site-profiles — is not collapsed, and keeps the iterated double Grothendieck of the profiled-base paragraph above. What remains, recorded in the ledger, is nesting (a System’s entire state as one variable of another), which is the same move aimed at the fibre. Nothing above depends on this paragraph.

## 9.10 The Semantic Universe, Assembled

The storeys are all built; this section states the building whole. The definition below is the chapter rendered as a single mathematical object: each clause names the storey it consumes and the section that built it.

**Definition 9.50** (The Semantic Universe). Fix a set of sites (clocks) and, for each site, a vocabulary of realized records carrying that site’s stamp (section 9.1–section 9.3). The **Semantic Universe** is the iterated double Grothendieck total

$$\mathbb{S}\mathbb{U} = \int (E \circ \mathcal{D}) \quad \text{— Specs over interfaces over site-profiles —}$$

the total, under the covariant span-valued double Grothendieck construction of section 9.9, of the composite of the profile-forgetting embedding  $E$  of the profiled wiring base into the fused wiring base with the coupled-DNF decoration functor  $\mathcal{D}$ . Unpacked, outermost layer first:

- *The outer indexing: site-profiles.* An object of the profiled base is an interface — a bundle of wires — together with a *site-profile*: an assignment of a site to each wire. Underneath every site sits the causal order (section 9.1), from which the site’s windows and coverage derive and on which its duration and tangency are declared (section 9.2); the profile is how that temporal geometry reaches the grammar of interfaces. Tight morphisms preserve profiles, and uniquely so — along a raw wire map into a profiled interface there is exactly one source profile making it profile-preserving — so the tight category of the profiled base is *discretely fibred* over site-profiles. This is the *first* Grothendieck integration: interfaces, integrated over site-profiles, as a fibration fact. The indexing is by profiles rather than by single sites (the mixed-boundary and clock-jitter arguments of section 9.9).
- *The middle base: interfaces and wirings.* Beneath the profile lies the fused wiring base of section 9.9: interfaces over the fused record vocabulary, wire maps as tight morphisms, wiring patterns as loose arrows — presented by their state families, with apex states restricting to boundary states — and pattern cells acting on apices. The embedding  $E$  forgets the profile. It is lax and not pseudo: its compositor is invertible, but its unit comparison embeds the profiled identity as the fused identity *pinned to the profile* — a genuine sub-pattern of the fused diagonal (section 9.9).
- *The fibres: presented constructible classes.* Over an interface, the decoration functor  $\mathcal{D}$  assigns the coupled-DNF presentations of constructible classes of belief bodies over that interface’s states. This clause compresses the tower: a record is an observation history over a window (section 9.3); the record carrier over each window is a compact Fell hyperspace in which records enter as graphs (section 9.4); a System denotes a belief — a lower semicontinuous functional on laws, its radial body a closed set of laws (section 9.5); the hyperspace of bodies makes Systems singleton elements (section 9.6); a Spec denotes a constructible class of bodies, a finite union of crescents closed under the connectives (section 9.7); and classes are carried window by window over the site, gluing as persistent families (section 9.8). The fibre holds *presentations*, not bare classes, because composition consumes presentations: the compositor is monotone in the presentation order and does not descend to semantic classes (section 9.9).
- *The second integration.* The double Grothendieck construction integrates these fibres over the profiled base — Specs over interfaces, stacked on interfaces over site-profiles. The two integrations compose into one total; naming them as they stack is the definition’s phrase “Specs over interfaces over site-profiles.”

Concretely, in the assembled total:

- an *object* is a site-profile, an interface over it, and a designated coupled-DNF presentation of a constructible class over the profile's fused states — which site each wire is on, what may be plugged where, and what is demanded of whatever is plugged;
- a *tight morphism* is a profile-preserving wire map together with the transport of the designated presentation — and the transport is not a choice: the projection below makes it unique;
- a *loose arrow* is a profiled wiring pattern with an apex presentation — a way of coupling two boundaries through a shared body of joint states, demands included;
- a *cell* is a pattern cell with transported decorations, and *loose composition* pairs the base composition of patterns with the compositor of presentations.

The strict projection  $\pi: \mathbb{S}\mathbb{U} \rightarrow (\text{profiled base})$  strips the decorations, and it is a *discrete double opfibration*: tight morphisms out of a fixed source and cells out of a fixed loose arrow lift uniquely. That is what the construction buys. Composition of Systems and Specs is never a design decision at use time — demands push forward totally along wirings, with no choices left to make and no side conditions owed to the site grading — and every pattern-level composition law of [chapter 13](#) has one place to discharge.

*Remark 9.51* (Mechanization status of the Semantic Universe). Kernel-checked, end to end, by one-line consumption of the generic Grothendieck theorems of [section 9.9](#) (the lifting calculus never inspects fibre internals, so the site grading costs it nothing): the iterated total is `SemanticUniverse` in module `SuFunctor.Spacetime.Universe` — the double Grothendieck total of `spacetimeSpecFunctor`, which is the landed decoration functor composed along the profile-forgetting embedding (`profiledEmbed`), with the pseudo double category instance (`semanticUniverse_pseudoDoubleCategory`) and the strict projection `pseudo` and a discrete double opfibration (`universeProj_isPseudo`, `universeProj_discreteOpfibration`). The profiled base and its unique profile lifts are `SuFunctor.Spacetime.Base` (`profileLiftHom`, `profile_unique_of_hom`); the embedding's laxity is by semantics, its faithfulness on tights a theorem (`profiledEmbed_faithful_tight`); and the fibres of the iterated object are the landed fibres *definitionally* (`spacetimeSpecFunctor_fibre_eq` is a `rfl`) — the construction's parametricity paying inside the indexed object. Per-site conservativity is packaged and pseudo: each one-site base sits inside the profiled base at the constant profile with tights, states, and patterns corresponding on the nose (`constProfile`, `constProfile_isPseudo`), and reading a presentation at one site is restriction along that packing (`siteRead`). Cross-site seams enter the fibres as wall conjuncts, exactly as in [section 9.9](#) (`SpecDnf.mem_modelClass_withWall`). The fused total — the double category of System Specs over the fused base, the development's `SingleSiteSemanticUniverse` — is the middle integration's total, and the headline object refines it by composing the site dimension into the base rather than leaving site data ambient in the states. What remains at design grade is unchanged from the composition section's own ledger: the monoidal layer's hypothesis package and the 2-categorical superstructure ([section 9.13](#)); nothing in this definition consumes either.

## 9.11 Adequacy: the Big Tent, Squared

A universe that claims to be a big tent owes each resident framework a receipt: a proof that compiling the framework's models into the toolkit and denoting them here agrees with interpreting them by the framework's own textbook semantics and *including* that semantics into this universe. The receipt has a fixed genre, the *adequacy square* ([Figure 9.5](#)), built so that squares are cheap to mint and impossible to hollow. Its *corners* are the literature's object (restated with the literature's own well-formedness fields, and tied where possible to a mechanized probability library's construction of the same object), the shipped compiled row grain (sparse conventions included, exactly as the emitters produce it), and this universe at the per-element stratum. Its *edges* are the shipped compile, the framework's own law, and the inclusion of precise models into the imprecise universe. The square's statement is an *invertible globular cell* in the thin double category of per-element semantic constraints — loose arrows are constraints on subprobability mass functions, loose composition is conjunction, cells are pointwise entailments — between denote-after-compile and include-after-interpret. The one contentful ingredient per square is a *feeding lemma*: the compiled constraint diagram pins the framework's law, exactly (finite-horizon Kolmogorov-extension content, spent once per engine).

Everything else is uniform packaging (`SuFunctor.Target`: the constraint double category;

Figure 9.5: The adequacy square, schematically. The left edge is the shipped compile, exactly as the emitters produce its rows; the top edge is the framework’s own semantics; the right edge is the inclusion of precise models into this universe; the bottom edge reads the compiled rows at the per-element stratum. The square’s statement is that the two composites agree — an invertible globular cell — and the feeding lemma is the one contentful ingredient: the compiled constraints pin the law, exactly.

`SuFunctor.Adequacy.Inclusions`: the inclusion library — singleton inclusion for precise frames, point-mass inclusion for deterministic ones, constraint-list conjunction with its definitional unit and cons laws, and the invertible-cell packager that turns a pointwise iff into the square).

Seven squares are kernel-checked at this writing, and each is stated in full — receipts included, most at the working scale of an exam problem with its sketch — in the section of the modelling catalogue (chapter 12) that presents its System-former or, in the delay line’s case, the wiring pattern that replaces one; the composition patterns that ride the squares cite them in place (chapter 13). Adequacy lives with the entry it certifies, and what this section keeps is the genre and the division of labour. The *Markov chain* square (`SuFunctor.Adequacy.Dtmc`; section 12.11) is the engine: one induction carries all the stochasticity, the compiled constraints force total mass one — a precise frame never draws on the universe’s native partiality, which is the “inclusion into the precise face” clause made a theorem — and a connector ties the exact-rational law to the mechanized probability library’s own construction. The *Bayesian network* square (`SuFunctor.Adequacy.Pgm`; subsection 12.20.1) is the same engine transposed from a time-line to a topological order, which is exactly what it was minted to demonstrate: nothing in the genre presumes time, because the genre is *parametric* over its trajectory carrier rather than indexed over the site — a square consumes only the carrier’s product structure, never an order on its coordinates — and where the site direction genuinely enters is exactly the two named gaps at this section’s close, not a hidden assumption inside any square. The *Markov decision process* square, fixed-policy face (`SuFunctor.Adequacy.Mdp`; section 12.13), is the first to reuse an engine wholesale — the chain square instantiated at the closed loop, no new induction, every stochasticity fact already spent — and the *demonic* (open-policy) face of the same class (`SuFunctor.Adequacy.MdpDemonic`, on the set-valued envelope vocabulary of `SuFunctor.Adequacy.EnvelopeUnion`; same section) is the first genuinely imprecise square: a set-valued bottom edge, one singleton inclusion per policy, reconciled with the credal reading through the radially maximal slice, with its degenerate cases mechanized. The *delay-line* square (`SuFunctor.Adequacy.DelayLine`; section 12.6) leaves the stochastic engines — the first spatially extended cell, making delay differential equations a wiring pattern rather than a formalism — and the *heat-on-torus* square (`SuFunctor.Adequacy.HeatTorus`, with the marginal-ring contrast in `SuFunctor.Adequacy.MarginalGlue`; section 12.5) is the first where the cover tier genuinely bites, the ring-closing wall carrying the mesh’s holonomy obligation. The seventh square (`SuFunctor.Adequacy.HeatTorusInit`; same section) ports the mesh square’s initial face as an exposed boundary trace along the window’s own filter, and, beside the squares, the set stratum of the same mesh is adjudicated rather than left to intuition (`SuFunctor.Adequacy.SolutionSetMesh`; same section), the first consumer of the record carrier’s equalizer-descent form: closed sets of records glue by exact descent while the point stratum’s holonomy wall goes wall-invisible there, and the missing datum is branch pairing — a named successor, not any pointwise constraint.

The squares also feed the universe this chapter assembles: the wiring stratum (`SuFunctor.Adequacy.SemanticUniverseWiring`) ties the stochastic squares to the coupled membership relation of the semantic universe’s fibres, per square, with no new induction — the squares’ feeding lemmas are consumed whole. Systems enter the fibres through one door, the radial wall of the precise constraint (`rwall_singletonC`): a law’s entry *is* its ray, the body of the precise belief in that law, and the judgment bridge is ray-shaped — a law’s entry meets a constraint’s wall atom exactly when the law satisfies the constraint

(`SuFunctor.Universe.RadialUniverse`; the bridge in three forms, unconditional at full mass). The wiring squares themselves are kernel-checked on the *slice* presentation of that entry (`idealPoint`: the wall vanishing at the law's joint alone, across the injective scalar seam `SubPMF.toJoint`), and the two presentations are verdict-equivalent against every radial constraint at every mass — the slice is the ray's radially maximal slice, the reconciliation the envelope stratum proves and the radial module sharpens: judged identically, the slice is nevertheless *not itself a member* of the universe (no belief compiles to a pinned point, `compile_ne_singleton`), so it is a computation device of the wiring stratum, never a denotation. Compiled diagrams become members of the fibre as single-disjunct DNF presentations (`diagramDnf`) whose safety face is the wall of the conjunction's image and whose liveness set is exactly the properness demand; and the membership bridge (`coupledSat_idealPoint_cwall_iff`) carries all four stochastic squares through one equivalence (`idealPoint_mem_diagramDnf_iff`) — membership of the law's entry in the compiled presentation's model class is equivalent to the law being the classical semantics, for the chain, the graphical model, the fixed-policy decision process, and, at the set stratum, the demonic face. Properness is free at every law's entry, the bottom law included — the lawful denotation of infeasibility is proper, and a jointly unsatisfiable compiled conjunction denotes the bottom body, never an exclusion of the inconsistent world (`contradictory_composite_denotes_bot`); no law enters as the inconsistent system, and the inconsistent system belongs to no presented diagram's model class. Two boundaries: the wiring is *per-carrier* — the fibre's record space is supplied directly, and the construction of the wire object from the compiled system is a separate, named stratum (the record-space tie below) — and the constraint walls are exact-stratum objects; the topological reading is the envelope stratum's successor, not built here.

Two disciplines govern every square, present and future. *Horizon*: the stochastic squares are stated at every finite horizon, with the  $\sigma$ -additive infinite-horizon extension (Ionescu–Tulcea) a named separate stratum, never smuggled; the differential squares are stated over open time windows, their record-tier content pointwise. *Envelope*: precise frames include by the exact singleton at the constraint stratum, and the reconciliation with the credal reading — the ray's maximal slice is the singleton, verdicts agree kind by kind, with the zero-law boundary and the down-closure hypothesis stated — is the kernel-checked bridge of Remark 9.23, composed once per square rather than re-proven; deterministic frames include their solution sets at the possibilistic stratum, with per-solution point-mass faces beside the set-level square. Beyond the seven kernel-checked squares, the future roster's cost is set by engine reuse and left-edge availability. Probabilistic logic programs (finite groundings, exact-rational) and declared-scheduler automata would ride the existing engines; continuous-time chains would split into an exact jump-chain face and a separately-stated holding-time stratum; input boxes and mixture formers would ride the set-valued envelope stratum the demonic square opened; stochastic-differential frames wait on their own analytic left edges; and the deterministic differential squares' finite/certificate and enclosure strata are un-mechanized successors with cost estimates recorded — estimates, not available squares. The two ties that would knit the squares to the record carrier and the site direction are the named gaps of the ledger: the *record-space tie* (the squares' trajectory carriers, supplied directly today, identified with the record loci of section 9.4 over the construction's base) and *horizon-pasting* (sequential composition of squares along the site direction, which is the construction's compositor read at the adequacy stratum).

## 9.12 The Wall Fragment: How Checked Verdicts Embed

The universe is now complete on its own terms: beliefs and their order, bodies and their hyperspace, constructible classes, fibres over the wiring base. This section is the adapter — everything about how the fragment the shipped checkers actually certify embeds into that universe is collected here, after the universe and before the receipts, so that no definition above owes anything to the checker and every checker fact below is an instance, not an axiom.

**Proposition 9.52** (The restriction theorem: walls). *Call a belief a wall when it is the indicator of a closed set  $C \subseteq \Delta_{\leq 1}(\mathcal{X})$  — zero on  $C$ , infinite off it; convexity is not part of the notion (the mechanized wall takes arbitrary closed sets), though every wall the shipped grammar denotes is in fact convex — half-spaces and their intersections — as a theorem, not a requirement. Every judgment kind of the shipped specification grammar denotes a wall at its carrier: the checker's valuation spaces are countable and discrete, where every event is clopen and both threshold polarities close, so the probability atoms  $P_{\geq p}[\varphi]$  and  $P_{\leq p}[\varphi]$  denote closed half-spaces of laws and sequent validity an intersection of such. (Over a general record space of the standing structure, event evaluation  $\mu \mapsto \mu(A)$  is not weakly continuous for arbitrary Borel  $A$ , and threshold sets close by the Portmanteau polarity discipline: lower bounds*

$\mu(A) \geq p$  give closed sets for closed events, upper bounds  $\mu(A) \leq p$  for open events; the grammar's event classes are chosen to obey it.) On walls the universe's order is equivalent to the classical verdict:  $\sigma \geq \chi_C$  iff every law admitted at finite height lies in  $C$ . The shipped checker's verdicts are comparisons in the universe's order, restricted to walls; nothing re-adjudicates under the graded reading.

**Proposition 9.53** (The bridge theorem: tolerance slices). *For any  $\sigma, \varphi: \Delta_{\leq 1}(\mathcal{X}) \rightarrow [0, \infty]$ ,*

$$\sigma \geq \varphi \iff \{\sigma \leq s\} \subseteq \{\varphi \leq s\} \text{ for every tolerance } s \in [0, \infty).$$

(Left to right is monotonicity of sublevels. Right to left, at each  $\mu$ : if  $\sigma(\mu) = \infty$  the inequality at  $\mu$  is automatic; otherwise instantiate  $s = \sigma(\mu)$ .) A graded comparison is therefore equivalently a family of crisp containments indexed by a rational tolerance — each slice a comparison of today's wall shape about a derived object — and this slice family is the graded order's certification chart: a producer may certify slices incrementally, while the composed claim remains the single domination statement.

**Why the universe grades at all, and what grading costs the checker.** The motivation is a muteness fact about the wall fragment: an indicator belief  $\chi_C$  and a graded ramp that vanishes at the centre of  $C$ , prices deviation within it, and is infinite off it receive *identical verdicts* from every wall — nothing expressible in the crisp fragment distinguishes a denotation from its indicator collapse, although the two describe different models. The graded order makes the landscape itself the subject. The cost: certifying  $\sigma \geq \varphi$  off the wall fragment is a named successor obligation for the certificate calculus, not shipped machinery. For belief data declared by rational polynomials over the law polytope — the finite-stratum carrier  $\Delta_{\leq 1}(V)$  is a rational polytope — domination is a single polynomial-nonnegativity obligation over a semialgebraic set, the certificate species this book's rule catalogue already discharges elsewhere, re-aimed; equivalently, by Proposition 9.53, per-slice containment rows with one added rational tolerance field (rational tolerances suffice: each real sublevel is the intersection of the rational ones above it). Until that obligation ships, the chapter's discipline is the claim ledger's: the wall fragment is shipped; the graded fragment is the semantics, argued and costed.

**Wall-blindness.** The wall fragment cannot see the gap between composition and conjunction (section 9.5's one inequality), a two-line fact: a finite sum in  $[0, \infty]$  is finite iff every summand is, so  $\{\sigma_1 + \sigma_2 < \infty\} = \{\max(\sigma_1, \sigma_2) < \infty\}$ ; and a wall comparison reads only the finiteness set ( $\sigma \geq \chi_C$  iff  $\{\sigma < \infty\} \subseteq C$ ). Sum-composition and join-composition therefore give identical verdicts against every wall — every exactness question the graded universe opens, it opens at the graded successor, and there as quantified conservatism in the safe direction, never as unsoundness. A companion invisibility governs convexity: against a convex Spec, a System and its biconjugate (greatest convex lower semicontinuous minorant) receive identical verdicts, so system-side non-convexity is invisible to single-shot linear tests while remaining composition-visible — the checker sees the convex reading, composition sees the territory, which is this book's untrusted-producer/trusted-checker split reappearing inside the semantics; a Spec whose content is not convex-expressible is certified through its own sublevel presentation, per-tolerance slice rows, rather than through an instrument that cannot see it.

**Where certificate rows enter the defining object.** This book works with the game-theoretic presentation of the glued global object (section 9.5) because certificates plug into it *definitionally*: the game-theoretic upper expectation is an infimum over bounded-below supermartingales dominating the target functional, and exhibiting a certificate  $V \geq 0$  whose floor rows dominate the indicator of the bad event and whose generator rows make it a supermartingale against the local credal data is exhibiting one element of the index set of the defining infimum — under one bookkeeping hypothesis that makes the membership literal: the limit-inferior condition is checked for the certificate's process stopped at the début of the bad region, and that stopped-process discipline is a per-mechanism-profile obligation, carried with the profile. With it,

$$\overline{P}(\text{bad}) \leq V(x_0), \quad \underline{P}(\text{safe}) \geq \underline{E}(1) - V(x_0),$$

a coherent lower-prevision bound, witnessed — and for full-mass denotations the familiar  $\underline{P}(\text{safe}) \geq 1 - V(x_0)$ ; the subtraction is the leak asymmetry of section 9.5, with its kernel receipts. The scheduler-uniformity a reader trained on nondeterministic model checking will look for is already inside the quantifier order: certificate rows carry the credal parameters symbolically over their declared regions, so a checked row holds for every element of every local credal set at once; fixing any compatible precise process makes

$V$  an ordinary supermartingale; the classical Ville–Doob inequality gives the per-element bound; and the bound passes to the envelope last. One quantifier, one direction, no interchange — and the checker verifies membership (sign conditions on polynomial rows), never the infimum itself; no completeness claim is made anywhere in the stack.

**The anchor: where a sequent verdict lives.** Every certificate in this book ultimately discharges into a checker verdict, and the verdict object is deliberately small: a sequent  $\Phi \vdash \Psi$  over an ambient hypernet (chapter 10), judged semantically valid over  $H$  when every admissible valuation of  $H$ ’s wires satisfying  $\Phi$  satisfies  $\Psi$  — the satisfaction clauses and the validity statement are stated once, with their mechanized counterparts quoted beside them, in chapter 15. The answer to *where* the verdict lives in this universe is exact and short: sequent validity is the wall-fragment restriction of the universe’s order, instantiated at the hypernet’s valuation space. It consumes no site structure — by design — and it consumes composition structure by inheritance; both statements are made precise below.

**The carrier.** Fix a hypernet  $H$ . A valuation assigns to each typed wire an exact tensor value of the wire’s declared type, and the valuation space  $\text{Val}(H)$  is the product of those countable discrete spaces — Polish by the standing structure. Admissibility and satisfaction each consult finitely many coordinates, so the three sets a verdict is about — admissible valuations, premise satisfiers, conclusion satisfiers — are cylinders over finitely many discrete coordinates, hence clopen. No temporal structure enters anywhere: a valuation is a single observation — a record with one stage — and the satisfaction clauses consume neither duration nor tangency. That is the site contract’s second freedom (*the checker never sees the site*) made visible in the semantics itself rather than promised at the format layer.

**The face.** Let  $B$  be the set of valuations the hypernet’s applications admit and the premise allows — closed, by the cylinder observation. Its possibilistic belief (Remark 9.22) is a wall, and under the order three readings of the verdict coincide:

$$\Phi \vdash \Psi \text{ semantically valid over } H \iff B \subseteq \{v \models \Psi\} \iff \bar{P}(\{v \not\models \Psi\}) = 0,$$

the checker’s quantifier, the behavioural superset test, and the degenerate face’s Boolean upper probability — equivalently, the order  $\sigma_{\text{scene}} \geq \sigma_{\text{sequent}}$  between the two walls, which is Proposition 9.52 at this carrier. The chain is kernel-checked at the exact stratum, stated as its two equivalences and their composite: the superset reading (`semanticallyValid_iff_subset`), the Boolean upper probability (`upperProb_eq_zero_iff`), and the composed face theorem (`semanticallyValid_iff_face`, module `SuFunctor.Plain.CheckerFace`). The corners agree too, and the agreement is where naive readings crack: when no admissible valuation satisfies  $\Phi$ , the sequent is vacuously valid, the wall is everywhere infinite, the compile is the bottom credal body — and the bottom body upper-bounds every event by zero (Remark 9.16), so the vacuous implication of the checker’s quantifier is the safety half of the denotation stratum’s bottom verdict, one fact in two dialects — itself kernel-checked as a named corollary of the face theorem: the compile of an unsatisfiable region is the bottom credal object (`suppIn_empty`), and the corner discharges through it (`face_ex_falso`). The agreement is lawful because sequent validity is an upper-envelope verdict throughout: the reading that refuses at bottom — the liveness reading, with its existential conjunct — is not one a sequent ever speaks. What the verdict deliberately does not exercise: the prevision pair never separates (nothing weighs valuations), partiality never bites (there is no mass to leak), and no belief grades (the face is crisp).

**No site structure by design; composition structure by inheritance.** The absence of site structure from the anchor is design (the second-freedom reading above), and the inclusion theorem preserves it: the anchor face factors through the one-stage stratum. Composition structure the anchor inherits: hypernets form a decorated-cospan double category, read through Patterson’s double-categorical lens [193] — loose arrows are cospans of wire contexts, the legs labelling the input and output wires, decorated by a wiring diagram on the apex — the anchor face is the object part of a lax double functor from that double category into the double category of System Specs (an open hypernet goes to its possibilistic coupling, the wall of its admissible-valuation set), packaged in the toolkit’s Lean tree as `hnetInclusion` (module `SuFunctor.HypernetDouble`): `opcartesian` lifts preserved on the nose, the compositor invertible exactly on the seam-disjoint stratum that content addressing guarantees for encoded hypernets, the unit comparison genuinely lax by conformance-pinning. The substitution laws of chapter 10 (Theorem 10.4) are exactly its

functoriality — with the determinism hypothesis of law (ii) deleted along the way, since the possibilistic face composes for the full calculus, `cell` included.

**What sits above the anchor.** The temporal and probabilistic instruments of this chapter are exercised by the *rules*, not by the verdict. A generator row’s meaning as supermartingale membership lives in the rule lemma that emitted it (the certificate paragraph above); the reading of an accepted sequent as a graded-order bound on a System’s denotation is the graded fragment, the named successor of Proposition 9.53. The factorization is the architecture’s own: the checker verifies membership — satisfaction over valuations, sign conditions on rows — and the deep semantic content lives in soundness lemmas quantified over every hypernet and every admissible valuation, one lemma per rule.

*Remark 9.54* (Mechanization status of the wall fragment and the anchor). Kernel-checked, over the general carrier of the semantic-universe strand — the statements are order-pure, and the mechanization consumes nothing of the record space (`SuFunctor.Universe.General.CheckerAnchor`): the wall restriction of the order (`sat_wall_iff`, `sat_wall_wall_iff` — Proposition 9.52) and the tolerance-slice bridge (`sat_iff_sublevel_subset` — Proposition 9.53). Kernel-checked, for the inclusion’s combinatorial core at the aligned stratum — the pushout-normal form where seam wires are literally shared — against the calculus’s own hypernet definitions (module `Qtsl.HypernetCospan`): loose composition of well-formed open hypernets with every boundary clause proved (`OpenHypernet`, `glue`), the admissibility split of a glued net — a valuation of the composite is admissible iff both parts’ applications hold, determinism nowhere (`glue_admissible_iff`) — and the unit and associativity laws on the nose (`unitOpen`, `glue_assoc`); the full-generality rename transport is kernel-checked in the same tree alongside the inclusion’s three other transformation laws (`theta_rename`, module `SuFunctor.HypernetInclusion`), and the double-category-library instantiation of the decoration functor is the packaged inclusion itself (`hnetInclusion`, module `SuFunctor.HypernetDouble`). Kernel-checked, in this repository’s certificate-calculus soundness development (the `Qtsl` package under `lean/qtsl`, whose per-rule statements [chapter 15](#) quotes beside each rule): the valuation, satisfaction, and validity definitions the anchor instantiates, and the theorem that every certificate object of the calculus witnesses its sequent’s semantic validity — total over the rule catalogue, by structural recursion with one lemma per rule (`ProofObject.sound`, with its checker-level face `check_sound`, module `Qtsl.Soundness`). The HOL4 development behind the certified checker (this repository’s `hol` tree) takes hypernet-level soundness as its trusted-statement target, and its composition toward the end-to-end theorem is in progress: demonstrated route, assembling now, and this section will say “machine-checked end to end” about that side only when it is.

## 9.13 Coherence Receipts

A chapter that promises “proven mathematically coherent” owes the reader its evidence classes, claim by claim. This book’s organizing principle — powerful untrusted producers, small trustworthy checkers — applies to its own metatheory, and this section is the application. Three evidence classes, fixed here and used in every mechanization remark of the chapter: *kernel-checked* means the named statements are theorems of this repository’s proof-artefact development; *prose-proven* means proven in adversarially reviewed prose in the development’s workshop record, not mechanized; *open obligations* are design with named obligations, stated in the future tense. In the claim-ledger vocabulary used across this book’s public surfaces, kernel-checked and prose-proven claims are [shipped] at their stated strata, open obligations are [argued], and this chapter contains no [aspirational] claims. Every kernel-checked claim lives in the toolkit’s proof-artefact repository, sorry-free at this writing, with the axiom census re-emitted at every build (each named theorem depends on at most propositional extensionality, choice, and quotient soundness; the forcing iff of [section 9.7](#) and the relational-transport core of [section 9.9](#) depend on no axioms at all). Two independent instruments keep the class checkable beyond the producing kernel: the repository’s `lean-cone` tool re-derives, for any named constant, a statements-only audit surface — the transitive signature cone, topologically sorted, elaborated against the real development — so the correspondence between this chapter’s prose and the tree’s statements is itself checkable without trusting either; and the compiled proof objects are re-checked by proof-checking kernels independent of the one that produced them (`SafeVerify`, and `nanoda`), so “kernel-checked” receipts are receipts from multiple kernels, not one.

**Kernel-checked.** By strand, one bullet per artefact layer, each named beside its statement in the body of the chapter:

- the double-categorical ambient: pseudo double categories with dependent cells and a cast calculus; lax double functors with the full coherence package; transformations and modifications assembling the functor double category; the loose bicategory bridge; companions, conjoints, and equipments; the span, matrix, and dependent-span models; the double Grothendieck construction at the dependent stratum, complete — total, strict projection, the split double opfibration development with canonical lifts and split laws as theorems, the discrete-opfibration interface, and the hom-level isomorphism between fiberwise transformations and strictly projection-compatible functors, choice-free; and the monoidal hypothesis package as decidable mixins over cyclic-group graded models, dependency table machine-checked;
- the wiring base in state-family presentation, with its reflexivity-valued transport calculus;
- the decoration tier, plain, site-indexed, and presentation-level: carriers, belief transport, the spec-class functor with all obligations at both strata, the coupled-DNF functor with atom-level transport, the atom-pairing compositor, and the option-A unit absorption, the assembled totals — the site-indexed class total and the authoritative `SingleSiteSemanticUniverse` — with strict projections and discrete double opfibrations by the generic theorems, the image-level comparison cells with their structure theorem, the constructible-fibre reading across the seam, the acceptance batteries (unit transparency, no funnel, associativity modulo base transport, ideal points monoidal, judgment as fibre order), and the refuting fixtures (taxed and funnel compositors, the unrepresentability pin, the matching fork);
- the record carrier: the Fell topology with hypothesis-free compactness; clip and proper-pushforward continuity with the seam fixture; descent as a homeomorphism onto the projective limit, with the nondirected and Vietoris sharpness fixtures; the record locus (single-timeline stratum) as a closed subsheaf with the speed-row and directedness fixtures and the Lipschitz-arc reading; the one-point compactification correspondence; the capacity presentation (basis, second countability, measure determination, separation, the frame form, and the two boundary fixtures); and class descent with constructibility in both directions;
- the universe and hyperspace storeys: carriers, membership closure, generation by rational rows, by tents, and by gamble rows at the general carrier, the pointwise order with its wall restriction and the tolerance-slice bridge, the order-level connective faces (conjunction's universal property; the functional-level minimum with its universal property and hedging witness), the coupled membership machinery with the blocking criterion (sound and complete, ex falso derived) and its incompleteness fixtures, the crescent and constructible-class calculus with the compile characterizations (the bijection with the credal bodies included), and the ideal-point/definability package;
- the transport stratum, at both the finite and the general carrier: the transport dictionary (body of a transported belief as body preimage), invariance of the coupled membership relation along surjections, the surjective structure theorem with its saturation condition, the non-surjective counterexample, the compositor's radial grade-product dictionary, and the union-distribution receipts;
- the disjunction stratum: the forcing iff (axiom-free), the countermodel schema, exactness and constructibility of the join, the disjunction property, the locally-closed-insufficiency witness, and the hedger fixtures separating the functional and class readings;
- the imprecise-probability strand of this repository: the belief-credal compile isomorphism (exact-rational, exp-free, with the concave-belief witness and the composition grade dictionary); the finite envelope-coherence package (attainment, super- and subadditivity, homogeneity, monotonicity); the additive law's domination and sublevel lemmas with their two fencing counterexamples, at the finite-rational stratum and space-free; the standard-Borel coupling-on-agreement theorem; the composition and tower laws of credal envelopes; the Hurwicz machinery with its composite evaluations; the belief-kernel tier at the exact stratum — tilted envelopes over signed costs with the credal zero-cost face and the one-member precise face, the positive-homogeneity failure witness, the finite Legendre transform of threshold profiles, the exact intertwining square with its two cost-law countermodels and the once-drawn diagonal's strict gap, the mixed-contraction identity with the strict exchange witness, wing collapse at prevision equivalence, and the Hurwicz chord decomposition with the certificate-pair rule and the finite-chords strictness witness; the coherent lower-prevision

- package with the finite envelope theorem and the natural extension's universal property, LP duality, and sure-loss alternative, with its four-mutant battery; the composition law's containment in the least-committal glue, with the crisp-locus iff and the strict rational witness; the feasibility (properness) equivalence at both strata with the exact conditional-product witness and its agreement-clause mutant; the leak-aware safe-side bound for submass models, envelope form and precise recovery, with the total-leak counterexample; and the credal-body poset of Remark 9.20 — placements, strict edges, and incomparability witnesses across the atlas's classes, the convexity adjudication trio (sufficiency, non-necessity, the boundary-jump closedness failure), and the prevision-ultracontribution identification;
- the generalization-column ledger items: the causal-diamond interior coverage (thickness iff and pair-filteredness at bicontinuous-poset generality), clock-map functoriality and cover-preservation with the homogenization core, and the open-quantum bounded-generator transport theorem with GKSL trace-annihilation and the Heisenberg trace adjunction;
  - the quantum strand of the causal-diamond column, at the finite-dimensional stratum throughout: the records-imply-consistency theorem at hypotheses weaker than projections, its additivity book-keeping, the load-bearing-hypothesis witnesses, the pure-state converse via branch projectors, a Minkowski instantiation, and the weakly-consistent-without-records witness; state-body gluing failure on the spacelike pair-cover with entanglement load-bearing (rigidity at pure marginals as the contrast), refusal of the failing cover by the derived topology, the general repair theorem (interior attainment implies separation), and the gap located at the linear rather than the multiplicative span; transport of diamonds, interiority, coverage, nets, separation, and determinacy along chronology-respecting order isomorphisms, with cover-preservation in the site-category vocabulary; the state presheaf with its separation and non-separation witnesses, the record shadow into probability rows with its strict credal band, and the unique-density-state representation theorem; Cauchy determinacy at both grades from complete initial data plus a reversible mechanism, its reversibility and exhaustiveness witnesses, and the frozen-shadow tie; the order-superposition probes (no records on a coherently switched index; pointer orthogonality classicalizes it); and the assembled locally covariant kinematic fragment with its two-qubit inhabitant;
  - the envelope reconciliation (ray versus singleton, with its boundary and refutation fixtures) and the seam isomorphism between the composition tier's and the judgment tier's carriers;
  - the cross-site stratum: the wall-conjunct criterion instances, the relational no-go kernel, the Egli-Milner lift with exact composition and the meets fixture, and the transport laws;
  - the site dimension in the base: the profiled base with its discrete fibredness over profiles, the profile-forgetting embedding (compositor invertible, unit comparison deliberately lax), the iterated total — Specs over interfaces over site-profiles — with its strict projection a discrete double opfibration, definitional fibre computation at the clocked instantiation, and the constant-profile equivalences of per-site conservativity;
  - the temporal-type-theory inclusion at the classical instantiation: the interval base site with the translation-quotient functor from the spec tier's windows (discrete-fibration lifts in both directions, covers corresponding to covers), the trajectory identification, the indicator calculus with behaviour-subtype spec objects, the judgment bridge (satisfaction as behaviour membership), strict tight intertwining, the compositor on indicators as span composition, and the semantically silent class-level laxity;
  - the certificate layer: the fibrewise-infimum transport dictionary at arbitrary carrier maps (safety adjunction, liveness transfer, the keystone factorization, transported model classes as preimages), unconditional transport monotonicity at both the semantic and the presentation order, the surjective dictionary re-derived as a one-line corollary, witness-gated composite certificates on the compositor, and the two fences (non-surjective ideal-point transport; presentation-sensitivity of the compositor);
  - the adequacy strand: the constraint double category, the inclusion library, the chain, Bayesian-network, and fixed-policy decision squares with mass theorems and library connectors, the demonic decision square with its set-valued bottom edge and the union-of-rays slice stratum, the delay-line square (delay differential equations as a wiring pattern, two-sided by the method of characteristics), the heat-on-torus square (the cover tier's cyclic mesh, with the holonomy wall and the frustrated-ring contrast) with its initial-face port (trace atoms, the conditional feed discharge, derived wrap-

compatibility), the solution-set mesh (exact equalizer descent consumed at the set stratum, the wall-invisible  $\mathbb{Z}$ -orbit holonomy witness), and the universe wiring (ideal points across the scalar seam, presented diagrams, the judgment bridge feeding the stochastic squares through the coupled judgment, and the singleton-versus-ray refutation);

- the checker anchor’s substrate: the certificate calculus’s valuation, satisfaction, and validity definitions with the per-rule soundness development, total over the catalogue (`ProofObject.sound` and `check_sound`, module `Qtsl.Soundness` of the `Qtsl` package), and the hypernet inclusion’s combinatorial core at the aligned stratum (open hypernets over the calculus’s own definitions, loose composition with well-formedness closure, the admissibility split, units and associativity on the nose, module `Qtsl.HypernetCospans`);
- the pointfree strand and the general stratum, landed as one campaign: valuations on frames with the promotion homeomorphism and the polarity package, the Borel bridge with  $\tau$ -additivity as its exact hypothesis class, bridge continuity into the pointfree carrier, and the free-ultrafilter escape witness; the classical subprobability carrier with the measure-level dagger chart, compactness by two independent routes, and metrizable; the general compile dictionary — closedness iff lower semicontinuity, the image characterization, unconditional reconstruction — with the general-carrier atlas placements, the grade-convexity criterion, the named order-closedness hypothesis of the finite-generation theorem, the Radon-functional tie at locally compact second-countable Borel carriers, and the general wall restriction and tolerance-slice bridge; subprobability Borel joints with the Giry-functor package, base-free coherence cores, the tight-tier general functor with its transposed battery and refutation pins, and the upward seam from the exact joints; the marginalization triple (escaping-mass witness, judgment-invisible reflector, tightness-certificate exactness) and the hull-closure package (closed binary hulls, levelwise coproduct exactness); the general-stratum composition containment with its crisp-locus characterization; the completed state-space category (all countable coproducts, disjoint and universal, with the bag space as the coproduct of its sorted-cone sectors); and the campaign’s continuation at the judgment and class tiers: the general connective faces, closure, and gamble-row generation (directed unconditionally; countable under second countability, discharged for compact metrizable record spaces), the general crescent and constructible stratum, the general transport dictionary with its named surjectivity and image-closedness supplies, the general demonic wall species with the cross-site criterion’s class exactness, and the general natural-extension package (envelope coherence over arbitrary nonempty families, the universal property at the definition’s stated scope with the dominating-family hypothesis self-certifying avoidance of sure loss, and closedness of the compatible set under continuous assessment gambles).

**Incorporated from the workshop.** A named minority of this chapter’s mechanized claims were, until their landing, *workshop-checked*: sorry-free kernel theorems whose modules lived in the development’s workshop tree pending incorporation, graded for a reader of this repository alone as adversarially reviewed prose with a mechanization attested. That set — the natural-extension package (universal property, linear-programming duality, sure-loss alternative, finite envelope theorem); the leak-aware safe-side package with its total-leak fixture; the containment theorem’s kernel form (crisp locus and strict rational witness); the packaged feasibility equivalence at both strata; and the site-column ledgers’ discharged items (interior-coverage pair-filteredness and the thickness equivalence at bicontinuous-poset generality, clock-map functoriality and cover-preservation, the homogenization core of time-inhomogeneity, and the open-quantum hypotheses’ transport theorem at the finite-dimensional stratum) — has been incorporated whole, as modules `QtslAux.Imprecise.NaturalExtension`, `QtslAux.Imprecise.Containment`, `QtslAux.Imprecise.FeasibilityGlue`, `QtslAux.LeakAware`, `QtslAux.DiamondSite`, and `QtslAux.OpenQuantum`, with axiom receipts emitted by the same build target as the rest of the package. As predicted at the staging, no claim of this chapter changed shape in the landing — only its evidence class; the workshop-checked class stands empty at this writing.

**Why the receipts are the doctrine: the phantom axiom.** The monoidal package’s original axioms do not imply the associator-interchange compatibility square: in graded models over an abelian group every coherence axiom linearizes, derivability becomes exact linear algebra, and the decision procedure exhibited a package satisfying every stated axiom, mediating cells invertible, whose associator-interchange square fails at explicit small integers. The repair is additive and costs every concrete instance nothing; the

audited dependency table is itself the exhibit — the new axiom is retained with its independence proven in both directions by machine witness, and a third candidate axiom turned out to be *derivable*: the audit removed an axiom thought necessary in the same pass that added the one that was missing. The lesson is drawn narrowly: in coherence axiomatics, a machine-decidable dependency table is the reliable form of the claim. That is why this chapter’s coherence claims cite kernel receipts, and why the disjunction stratum’s own repair went through the same door: the failure was found by countermodel, generalized into a kernel-checked schema, and only then written into prose.

**Prose-proven, adversarially reviewed.** The localic reading of the fibre column (the powerlocale and valuation-locale identifications, geometricity of the layer-by-layer presentation) — though no longer with the mechanized tier confined to its point-set shadow: the capacity presentation’s determination theorem and the valuation layer beneath it are kernel-checked at the localic stratum (Remark 9.13, Remark 9.36); the site-column mathematics not yet in the kernel (the causal-diamond column’s manifold-level instantiation of the clock-map hypotheses; the open-quantum column’s design hypotheses); the 2-categorical superstructure of the change-of-base layer; the span-of-categories generality of the Grothendieck construction (consumed by nothing in the shipped construction); and the classical agreement theorems’ prose legs at their stated finite-state, discrete-time scope; the collapse theorem for the certificate storey (fixed site, ordered fibres, the comma reading of the iterated construction), whose instantiation at the landed fibres is the kernel-checked certificate layer above; and the hypernet inclusion’s three theorems at full generality — the decorated-cospan double category of raw wiring diagrams, the well-formed genus as a sub-double category closed under composition, and the strict double-functorial inclusion via the possibilistic coupling — with their combinatorial core kernel-checked at the aligned stratum. An entity-level decoration functor — windowed System fibres, coupling categories, five prose-verified axioms — remains in the workshop record at this grade as the design basis of the certificate layer’s refinement stratum; the construction’s definition is the kernel-checked functor pair of section 9.9, and no claim of this chapter leans on the entity-level construction.

**Open obligations, with names.** The remaining gaps, so the reader need not hunt for them — and there are several, not one. The graded order’s checker obligation: certifying belief domination off the wall fragment (polynomial nonnegativity over the law polytope, or equivalently slice-containment rows with a tolerance field), the [argued] line of Proposition 9.53, with the wall fragment shipped. The site-indexed re-instantiation of the presentation fibres (the packaging step of section 9.9), and the two transport residues of Remark 9.49: closedness of the saturation locus, and non-surjective image constructibility. The cartesian half of the projection (preimage-transport lifts; the image-preimage adjunction on class fibres) and the two-sided form with the site as a visible index. The record-space tie and horizon-pasting for the adequacy squares (section 9.11). The Fell-carrier form of the window assembly (section 9.8): the extension calculus, its presheaf laws, both exchange theorems, and the persistence closure package — kernel-checked today over the function presentation of the trajectory carriers, graphs before closure under the product  $\sigma$ -algebra — restated over the record carrier itself, with Borel-on-Fell as the measurability datum and the carrier’s Fell-continuous clip as the restriction (the embedding being graph-then-closure, so that the presented calculus becomes the restated one’s image along the presentation); the clip’s own measurability is already a corollary of its landed continuity. The pair-sequent packaging of the blocking criterion. The  $\sigma$ -completion of the class fibre (section 9.7): attitude superlevels and threshold families as unions of crescents over declared index families, with transport carrying semicontinuity certificates for both envelope passes. The body-level representation of non-radial members (the classes quantify over bodies, which are radial objects; the graded universe’s two-axis members await their own body construction there). The hybrid (multivalued-instant) event strata — the shadow of the compact parameter class closed as a continuous image, and the alternation-bounded classes closed by hit-face arithmetic — plugging into the kernel-checked generic local-locus interface; should a clause family ever certify same-instant sequencing, the lens adjoins an event face by the same con-coupling that adjoined the measure face, and nothing below re-plumbs. The record locus over general causal supports (Definition 9.8) — where the single-timeline slicing argument does not bundle: over chronologically thick supports, two-point specimens refute closedness of the full record class (a spacelike stage-pair Fell-converging onto a null pair awakens a zero-duration constraint no approximant felt; a merging spacelike pair defeats single-valuedness), so what is owed is the factored replacement. Closedness of the interior-pair locus — speed bounds over pairs in the interior of comparability, which push-up identifies with chronology — by the same violating-pair margin argument, consuming two site hypotheses: chronology open in the stage topology, and

the two-stage duration upper semicontinuous on it (on a globally hyperbolic instantiation: openness of  $I^+$ , with the interval topology the manifold topology, and continuity of the Lorentzian distance). The plug of that locus into the kernel-checked local-locus interface, whose directedness step is unchanged. Closedness of the single-timeline-support sub-locus, where chain supports are Fell-stable because causality is closed. And the zero-duration-pair and single-valuedness conditions as certified  $G_\delta$  strata inside the closed locus, carried in the manner of the Zeno stratum rather than by the topology. The outer storey of the background-independent column (section 9.2): morphisms beyond isomorphisms and coverage for order-indexed sites — transport along chronology-respecting order-isomorphisms is kernel-checked above — together with the quantum column's named residues: relative Cauchy evolution and the stress-energy tensor, where the kinematic fragment fences off dynamics proper; non-surjective embeddings between different spacetimes, with functoriality of the assembled fragment along them; and the reading of the fragment's record shadow into the belief storey at a constant site-profile. The prevision-sheaf face of the fibre column and the fully typed display of the monoidal package's batched discharge rows, with the mechanical comparison identifying the Grothendieck-route coherences with the classical decorated-cospan components — and, for the hypernet inclusion of section 9.12, the full-generality rename transport and the double-category-library instantiation of its decoration functor. The logic-site contract's remaining transports: the analytic half of the extension-theorem audit (objectwise-classical, per window class), the probabilistic time-inhomogeneity lemma's projective-limit step, and the open-quantum event/record transport theorem. The HOL4 certified checker's end-to-end composition over the anchor's validity statement: demonstrated route, assembling now. And nesting — a System's entire state as one variable of another, named in section 9.9 — together with the library-grade generic form of the certificate storey's collapse (the ordered-fibre double Grothendieck with its comma isomorphism), whose instantiation at the landed fibres is kernel-checked above. Each entry above is stated in the future tense, deliberately, and nothing downstream in this book consumes any of them ahead of their receipts.

# Hypernets: Primitive Functions

DRAFT

Three strata of this book each need, at some point, a notion of *computation*. A System (chapter 12) declares mechanisms whose fields — drift laws, guard conditions, reset maps, neural controllers — are computational objects. A specification (chapter 9) asks whether observables computed from a trajectory stay inside a region, and a certificate about it carries polynomial content of its own. The rule catalogue (chapter 15) states every inference rule over “the ambient hypernet” — a typed computation graph that each rule reads facts out of. If those three strata each invented their own computational syntax, the toolkit would own three evaluators, three serialization schemes, and three subtly different answers to “is the function the certificate reasons about the function the system runs?”

It owns one. The shared object is the *hypernet*: a typed, exactly representable computation graph built from ten primitive boxes, with one evaluator, one canonical serialization, and one content digest. Everything in the toolkit that computes — an ODE right-hand side, a ReLU network, a guard observable, the goal polynomial of a Lyapunov certificate — either *is* a hypernet or elaborates into one by a definitional translation. This chapter defines the object once, so that the rest of the book can consume it by reference: the representation and its well-formedness discipline (section 10.1); the ten boxes themselves (section 10.2); the completion theorem that fixed their number at ten (section 10.3); the plate extension, under which one finite graph denotes a function of variable-dimensional state — symbolic extents, not an eleventh box (section 10.4); the single-genus design rule and the view/elaboration discipline it imposes on every other computational syntax (section 10.5); the substitution operation under which hypernets compose, with its coherence and digest laws (section 10.6); the precise sense in which Systems, specifications, and rules all consume the same genus (section 10.7); and the kinship between the graph-side contraction box and the relational engine’s contraction rows (section 10.8). A closing ledger (section 10.9) states which claims in this chapter are machine-checked, which are proven in prose with executable witnesses, and which remain in the design tense.

This chapter is also the toolkit’s *Primitive Catalogue*. Each of its thirteen rows — the ten boxes, the container, the substitution operation, and the well-formedness preflight — carries an anchored entry inside the narrative below, stating the row in compact metanotation and quoting its producer API, TypeScript then Rust. The metanotation statements are typeset by hand for notational quality; their mechanized ground truth is the catalogue’s per-box typing rules and well-formedness predicates, realized twice and in agreement (section 10.9). The API blocks are generated, never hand-quoted: signatures are re-extracted from the toolkit sources at every regeneration, and every construction snippet is quoted verbatim from the conformance corpus whose emitted canonical bytes are verified byte-identical against the reference implementation’s golden vectors.

A reading map, since the chapter doubles as reference material: on a first pass, read the representation (section 10.1), the table that opens section 10.2, the completion theorem of section 10.3 (a self-contained story), and the single-genus rule of section 10.5; return to the per-box catalogue entries as later chapters cite them, and leave the plate extension (section 10.4) until the token-population models of section 12.18 send you back for it. The mathematics is newest in the plate extension and in section 10.7, where the chapter’s compositional claims assemble into one machine-checked inclusion theorem (Theorem 10.6).

## 10.1 The intermediate representation

A hypernet is a dataflow graph over *tensor-typed wires*. A tensor type  $\langle s, \delta \rangle$  pairs a shape  $s$  (a finite list of extents; scalars have the empty shape  $[]$ ) with a dtype  $\delta$  — Boolean, integer, or exact rational  $\mathbb{Q}$  in the configurations this book uses. Exactness is a design commitment, not an optimization default: constants

enter as exact rationals,<sup>1</sup> the reference evaluator computes in  $\mathbb{Q}$ , and any change of numeric representation must pass through an explicit box with a declared rounding mode. There is no ambient floating-point semantics for a certificate to be quietly wrong about.

**Definition 10.1** (hypernet). A hypernet consists of: a *wire-type table* assigning each wire a tensor type; a pool of simplicial complexes (the payloads of the branching box, section 10.2.4); a finite sequence of *applications* of the ten primitive boxes of section 10.2, each consuming named input wires and producing named output wires; and an *interface*: an ordered list of graph inputs and an ordered list of graph outputs. It is *well-formed* when three conditions hold:

- **linearity** — every wire is produced by at most one application (graph inputs by none) and consumed by at most one;
- **acyclicity** — applications are listed in static-single-assignment order: every consumed wire is a graph input or the output of an earlier application;
- **type consistency** — each application satisfies its box’s typing rule (stated per box below).

All three conditions are decidable by direct inspection of the ground data, and both realizations of the IR — the Lean structure, which carries the three conditions as fields, and the reference implementation, which checks them — enforce them at the same strength.

### the well-formedness preflight

Primitive Catalogue entry H-WF

The row (Computer Science Metanotation)

$$\frac{\text{linearity}(H) \quad \text{acyclicity}(H) \quad \text{every application satisfies its box's typing rule}}{\text{wf}(H)} \text{WF}$$

All three conjuncts are decidable predicates over the ground data of Definition 10.1; the preflight operation decides them and returns the (possibly empty) list of violations, each carrying its geometry — the offending wire, application index, or typing fact. It is a producer-side courtesy: the checker replays the same conditions independently and believes only its own verdict.

## API

Producer surface of the mtk toolkit for this catalogue entry: the TypeScript arrangement (npm package @maitria/mtk, hypernet namespace) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this block; each construction is quoted verbatim from the toolkit’s hypernet conformance corpus, code whose emitted canonical graph bytes are verified byte-identical against golden vectors generated by the reference implementation (the corpus’s fixture graphs — an all-ten-primitives graph, an identity, a substitution composite, and the fifteen-application drift of this chapter’s worked example — are the receipts). This API constructs and emits; it never checks — the checker re-derives every claim independently. Later entries of this catalogue cite this note rather than repeating it.

Courtesy check: the returned list is every violation found, and empty means the linearity, SSA, and per-primitive typing conditions hold and every pooled complex validates — but the checker’s replay is the authority, never this preflight. The corpus construction validates the worked example’s fifteen-application drift graph.

**TypeScript** `hypernet.Hypernet.preflight`

signature — `ts/src/hypernet.ts`

| `preflight(): ReadonlyArray<Violation>`

construction — `ts/tests/hypernet-native.test.ts`

<sup>1</sup>An IEEE float read from a model file denotes a dyadic rational and is stored as one, losslessly; the ACAS Xu import of section 10.9 carries every published network weight this way.

```
const h = hn.unwrap(hn.Hypernet.fromCanonicalBytes(hypernetGolden("g3_cartpole_drift")));
assert.equal(h.preflight().length, 0);
assert.equal(h.appCount, 15);
```

**Rust** `mtk_catalogue::hypernet::Hypernet::preflight`

signature — `crates/mtk-catalogue/src/hypernet/wf.rs`

```
pub fn preflight(&self) -> Vec<Violation>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
let h = Hypernet::from_canonical_bytes(&golden("g3_cartpole_drift")).unwrap();
assert!(h.preflight().is_empty());
assert_eq!(h.apps.len(), 15);
```

Linearity is the load-bearing choice. In most graph formats, sharing a value is implicit (draw two edges out of a node) and discarding one is invisible (draw none). Here both are rows: fan-out is the copy box, fan-in is the stack box, discard is the delete box, and exchange is the swap box. The payoff is that structure becomes syntax — how many times a value is used, and where, is readable off the application list without any analysis pass, which is what lets the substitution operation of section 10.6 repair seams mechanically and lets well-formedness be preserved by a proof rather than a linter.

A well-formed hypernet is a *string diagram*: boxes are the typed, multi-input multi-output operations, wires carry the content, and two parallel wires between the same boxes are genuinely distinct. Combinatorially, string diagrams over a symmetric monoidal signature correspond to typed hypergraphs with interfaces, and the directed, Frobenius-free fragment is carved out by exactly two conditions — monogamy and acyclicity (Bonchi, Gadducci, Kissinger, Sobociński, and Zanasi [27]; the companion paper [26] treats the unrestricted setting) — which are the linearity and SSA conditions above under other names. “Hypernet” names this object with its interface and canonical serialization made first-class.<sup>2</sup>

Two near neighbours locate the design choice. Keeping monogamy makes an application list a term of the free symmetric monoidal syntax on the box signature, in which sharing, discarding, and ordering are rows. Dropping the consumer half of monogamy would give the *gs-monoidal* setting of term graphs, in which fan-out is absorbed into the wiring [84]; dropping the producer half as well would give hypergraph categories [26], in which a twice-produced wire asserts an equation rather than carrying a value. The calculus stays in the first setting because its consumers are certificates: how many times a value is used, and where, must be readable off the bytes without an analysis pass. The choice costs plumbing rows in the graphs. It does not cost composition: gluing two hypernets along a shared interface inserts no structural row at all, a fact section 10.6 states and the Lean tree checks.

Serialization is part of the definition’s job description, because certificates refer to computations by content. Every well-formed hypernet has a canonical byte serialization — wire ids assigned by first appearance, complex pool deduplicated, evaluator hints and debug names excluded — and its *digest* is the SHA-256 hash of those bytes. Two design consequences are worth stating before the boxes: equal digests certify equal computation graphs, not merely equal functions (two different graphs computing one function deliberately do *not* share a digest; extensional equality of programs is not decidable, and the digest never pretends otherwise); and every certificate row that cites a computation cites it by digest, so “which function is this claim about?” has a content-addressed answer.

## the container

Primitive Catalogue entry H-GRAPH

### The row (Computer Science Metanotation)

$$H = \langle W, \mathcal{K}, A, in, out \rangle \qquad \text{digest}(H) = \text{SHA-256}(\text{canon}(H))$$

The record of Definition 10.1: wire-type table  $W$ , complex pool  $\mathcal{K}$ , SSA application list  $A$ , interface  $(in, out)$ . The canonical serialization `canon` assigns wire ids by first appearance, deduplicates the pool, and excludes evaluator hints and debug names; equal digests certify equal graphs, never merely equal functions.

<sup>2</sup>The name comes from the graph-machine school that coined it [8, 89], whose hypernets are likewise monogamous directed hypergraphs. There the interface is read off vertex degrees; here it is declared data, and the canonical serialization is new.

## API

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

The trio quoted here is the container's content-address surface — strict decode, canonical bytes, SHA-256 digest; a graph is closed by `HypernetBuilder::finish` (TS `Builder.finish`), which runs the full preflight as a belt. The construction quoted below is the corpus's decode-re-encode-digest loop over the four committed reference vectors.

### TypeScript `hypernet.Hypernet`

signature — `ts/src/hypernet.ts`

```
static fromCanonicalBytes(bytes: Uint8Array): Result<Hypernet, CanonRefusal>

canonicalBytes(): Result<Uint8Array, CanonRefusal>

digest(): Result<HypernetDigest, CanonRefusal>
```

construction — `ts/tests/hypernet-native.test.ts`

```
const h = hn.unwrap(hn.Hypernet.fromCanonicalBytes(golden));
const re = hn.unwrap(h.canonicalBytes());
assert.equal(toHex(re), toHex(golden), "native re-encode");
assert.equal(hn.unwrap(h.digest()), manifest.fixtures[name]!.sha256, "native digest");
```

### Rust `mtk_catalogue::hypernet::Hypernet`

signature — `crates/mtk-catalogue/src/hypernet/canon.rs`

```
pub fn from_canonical_bytes(bytes: &[u8]) -> Result<Hypernet, CanonRefusal>

pub fn canonical_bytes(&self) -> Result<Vec<u8>, CanonRefusal>

pub fn digest(&self) -> Result<HypernetDigest, CanonRefusal>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
let bytes = golden(name);
let h = Hypernet::from_canonical_bytes(&bytes)
    .unwrap_or_else(|e| panic!("{name}: decode refused: {e}"));
let re = h.canonical_bytes().unwrap();
assert_eq!(re, bytes, "{name}: re-encode differs from golden bytes");
assert_eq!(
    h.digest().unwrap().to_hex(),
    manifest_digest(name),
    "{name}: digest differs from manifest"
);
```

## 10.2 The ten primitive boxes

The calculus has ten primitive boxes. Constructor order in the mechanized catalogue and tag order in the wire format agree (tags 0–9), and the order below follows them. Throughout,  $\langle s, \delta \rangle$  is a tensor type,  $\mathbb{B}$  abbreviates the Boolean scalar type  $\langle [], B \rangle$ , and  $k::s$  is the shape  $s$  with a new leading axis of extent  $k$ .

|   | box                    | signature                                                                                                 | one-line semantics                 |
|---|------------------------|-----------------------------------------------------------------------------------------------------------|------------------------------------|
| 0 | <code>const</code>     | $\emptyset \rightarrow \langle s, \delta \rangle$                                                         | emit a literal tensor              |
| 1 | <code>contract</code>  | $\langle s_1, \delta \rangle, \dots, \langle s_k, \delta \rangle \rightarrow \langle s_0, \delta \rangle$ | sum of products over bound indices |
| 2 | <code>cast</code>      | $\langle s, \delta \rangle \rightarrow \langle s, \delta' \rangle$                                        | change dtype, declared rounding    |
| 3 | <code>cell</code>      | $\langle [d], \mathbb{Q} \rangle \rightarrow \mathbb{B}, \dots, \mathbb{B}$                               | one-hot region membership          |
| 4 | <code>reshape</code>   | $\langle s, \delta \rangle \rightarrow \langle s', \delta \rangle$                                        | same entries, new shape            |
| 5 | <code>broadcast</code> | $\langle s, \delta \rangle \rightarrow \langle s', \delta \rangle$                                        | replicate along new axes           |
| 6 | <code>copy</code>      | $\langle s, \delta \rangle \rightarrow \langle s, \delta \rangle^k$                                       | explicit fan-out                   |
| 7 | <code>delete</code>    | $\langle s, \delta \rangle \rightarrow \emptyset$                                                         | explicit discard                   |
| 8 | <code>swap</code>      | $\tau_1, \tau_2 \rightarrow \tau_2, \tau_1$                                                               | exchange two wires                 |
| 9 | <code>stack</code>     | $\langle s, \delta \rangle^k \rightarrow \langle k::s, \delta \rangle$                                    | explicit fan-in: new leading axis  |

Nine of the ten are deterministic, total, single-valued operations. `cell` is the deliberate exception: *the calculus's only source of disjunction*. Every case split a hypernet can express — the two sides of a ReLU, the five advisory regions of a collision-avoidance policy — is some `cell` application's one-hot output, and every downstream consumer of a case split can be traced to it. A checker that must reason by cases knows, syntactically, where all the cases come from.

### 10.2.1 Sources and the multilinear engine: `const` and `contract`

`const` takes no inputs and produces one wire of a declared type, carrying a literal value: network weights, gain matrices, sign vectors, the all-ones vector that turns a `stack` into a sum (section 10.3). All numeric literals are exact rationals. Constants are applications like everything else — a hypernet's parameters are part of its graph, hence part of its digest.

**const**

Primitive Catalogue entry H-CONST

The row (Computer Science Metanotation)

$$\frac{v \text{ a literal of type } \langle s, \delta \rangle \text{ (row-major, size}(s) \text{ entries, exact)}}{\text{const}_v : \emptyset \rightarrow \langle s, \delta \rangle} \text{const}$$

Semantics:  $\text{out} = v$ . Tag 0; the only zero-input box.

## API

Producer API of the `mtk` toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

The exact-rational constant is quoted; the Boolean flavour (payload of bits) is constructed in the same corpus fixture, a few lines below the quoted one.

**TypeScript** `hypernet.Builder.constant`

signature — `ts/src/hypernet.ts`

```
constant(
  ty: TensorType,
  entries: ReadonlyArray<QLike> | ReadonlyArray<boolean>,
): Result<Wire, BuildRefusal>
```

construction — `ts/tests/hypernet-native.test.ts`

```
const c1 = hn.unwrap(b.constant(hn.rat([2]), ["3/2", "-7/3"]));
```

**Rust** `mtk_catalogue::hypernet::HypernetBuilder::constant`

signature — `crates/mtk-catalogue/src/hypernet/graph.rs`

```
pub fn constant(&mut self, ty: TensorType, value: ConstPayload) -> Result<Wire, BuildRefusal>
```

construction — crates/mtk-catalogue/tests/golden\_hypercent.rs

```
let c1 = b
  .constant(
    TensorType::rat([2]),
    ConstPayload::Rat(vec![q(3, 2), q(-7, 3)]),
  )
  .unwrap();
```

**contract** is the entire multilinear engine: the  $n$ -ary generalized Einstein summation, with its index structure carried as explicit data rather than inferred from a notation string.

**Definition 10.2** (contraction pattern). A contraction pattern for inputs of ranks  $r_1, \dots, r_k$  and output rank  $r_0$  consists of a finite index set  $I$ , an extent  $E_i \in \mathbb{N}$  for each  $i \in I$ , a binding  $\beta_m: \{0, \dots, r_m-1\} \rightarrow I$  for each input  $m$ , and a binding  $\beta_0: \{0, \dots, r_0-1\} \rightarrow I$  for the output; type consistency requires every bound axis's extent to equal its index's extent. Writing  $\nu\beta$  for the coordinate tuple obtained by composing an index assignment  $\nu \in \prod_{i \in I} \{0, \dots, E_i-1\}$  with a binding  $\beta$ , the semantics is

$$\text{out}[c] = \sum_{\nu: \nu\beta_0=c} \prod_{m=1}^k \text{in}_m[\nu\beta_m].$$

Matrix product is a contract ( $ai, ij \rightarrow aj$  in einsum notation); so are dot products, traces, elementwise products, tensor products, and axis sums. Two structural facts about this box do quiet work later. First, a rank-0 input has no axes to bind but still contributes its single entry as a factor to *every* term of the sum — scalars multiply in; they do not add in. Second, and in the same direction: every term of every output entry contains a factor from *every* input wire. **contract** is purely multiplicative across wires, and section 10.3 turns that observation into a theorem about what the box cannot do.

**contract**

Primitive Catalogue entry H-CONTRACT

The row (Computer Science Metanotation)

$$\frac{\beta = (I, E, \beta_0, (\beta_m)_{m=1}^k) \text{ a contraction pattern (Definition 10.2)} \\ \text{each bound axis's extent equals its index's extent}}{\text{contract}_\beta: \langle s_1, \delta \rangle, \dots, \langle s_k, \delta \rangle \rightarrow \langle s_0, \delta \rangle} \quad \text{contract}$$

Semantics: Definition 10.2's sum of products,  $\text{out}[c] = \sum_{\nu: \nu\beta_0=c} \prod_m \text{in}_m[\nu\beta_m]$ . Tag 1; the entire multilinear engine, index structure as explicit data.

## API

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

**TypeScript** `hypernet.Builder.contract`

signature — ts/src/hypernet.ts

```
contract(
  inputs: ReadonlyArray<Wire>,
  bindings: {
    extents: ReadonlyArray<number>;
    inBindings: ReadonlyArray<ReadonlyArray<number>>;
    outBinding: ReadonlyArray<number>;
  },
): Result<Wire, BuildRefusal>
```

construction — ts/tests/hypernet-native.test.ts

```
const d = hn.unwrap(
  b.contract([x, c1], { extents: [2], inBindings: [[0], [0]], outBinding: [] }),
);
```

**Rust** `mtk_catalogue::hypernet::HypernetBuilder::contract`

signature — `crates/mtk-catalogue/src/hypernet/graph.rs`

```
pub fn contract(
  &mut self,
  inputs: &[Wire],
  extents: &[u64],
  in_bindings: &[Vec<u32>],
  out_binding: &[u32],
) -> Result<Wire, BuildRefusal>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
let d = b
  .contract(&[x, c1], &[2], &[vec![0], vec![0]], &[])
  .unwrap();
```

## 10.2.2 Representation moves: cast, reshape, broadcast

**cast** converts dtype at fixed shape, carrying an explicit rounding mode. It is the only box at which numeric representation changes, which localizes every exactness argument: a hypernet with no cast (or only exact ones, such as the Boolean-to-rational conversion that turns an indicator into a gate) computes in  $\mathbb{Q}$  end to end, and one carrying rounding casts declares, in its syntax, where error can enter.

**cast**

Primitive Catalogue entry H-CAST

The row (Computer Science Metanotation)

$$\frac{\rho \text{ a declared rounding mode for } \delta \rightarrow \delta'}{\text{cast}_{\delta \rightarrow \delta', \rho} : \langle s, \delta \rangle \rightarrow \langle s, \delta' \rangle} \text{ cast}$$

Semantics: entrywise conversion under  $\rho$ ; exact casts (the Boolean-to-rational indicator gate among them) introduce no error. Tag 2; the only box at which numeric representation changes.

## API

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

**TypeScript** `hypernet.Builder.cast`

signature — `ts/src/hypernet.ts`

```
cast(inp: Wire, to: Dtype): Result<Wire, BuildRefusal>
```

construction — `ts/tests/hypernet-native.test.ts`

```
const ci = hn.unwrap(b.cast(bc, hn.INT));
```

**Rust** `mtk_catalogue::hypernet::HypernetBuilder::cast`

signature — `crates/mtk-catalogue/src/hypernet/graph.rs`

```
pub fn cast(&mut self, inp: Wire, to: Dtype) -> Result<Wire, BuildRefusal>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
let ci = b.cast(bc, Dtype::INT).unwrap();
```

**reshape** re-indexes a tensor’s entries into a new shape of the same total size — row-major order, no data motion in the semantics. **broadcast** replicates along new or singleton axes, under the trailing-axis compatibility rule familiar from array programming; the result is constant along each broadcast axis. Both are plumbing; they let contract patterns stay simple by normalizing operand shapes, and their semantics are entry-relabelling and entry-duplication, contributing no arithmetic of their own.

**reshape**

Primitive Catalogue entry H-RESHAPE

**The row (Computer Science Metanotation)**

$$\frac{\text{size}(s') = \text{size}(s)}{\text{reshape}_{s'} : \langle s, \delta \rangle \rightarrow \langle s', \delta \rangle} \text{ reshape}$$

Semantics: the same entries under row-major re-indexing; no data motion. Tag 4.

**API**

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue’s first entry](#).

**TypeScript** `hypernet.Builder.reshape`signature — `ts/src/hypernet.ts`

```
| reshape(inp: Wire, newShape: ReadonlyArray<number>): Result<Wire, BuildRefusal>
```

construction — `ts/tests/hypernet-native.test.ts`

```
| const r = hn.unwrap(b.reshape(t, [3, 1]));
```

**Rust** `mtk_catalogue::hypernet::HypernetBuilder::reshape`signature — `crates/mtk-catalogue/src/hypernet/graph.rs`

```
| pub fn reshape(&mut self, inp: Wire, new_shape: &[u64]) -> Result<Wire, BuildRefusal>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
| let r = b.reshape(t, &[3, 1]).unwrap();
```

**broadcast**

Primitive Catalogue entry H-BROADCAST

**The row (Computer Science Metanotation)**

$$\frac{s \leq s' \text{ (trailing-axis compatible)}}{\text{broadcast}_{s'} : \langle s, \delta \rangle \rightarrow \langle s', \delta \rangle} \text{ broadcast}$$

Semantics: replication along the new and singleton axes; the result is constant along each broadcast axis. Tag 5.

**API**

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue’s first entry](#).

**TypeScript** `hypernet.Builder.broadcast`signature — `ts/src/hypernet.ts`

```
| broadcast(inp: Wire, toShape: ReadonlyArray<number>): Result<Wire, BuildRefusal>
```

construction — ts/tests/hypernet-native.test.ts

```
| const bc = hn.unwrap(b.broadcast(r, [3, 2]));
```

**Rust** mtk\_catalogue::hypernet::HypernetBuilder::broadcast

signature — crates/mtk-catalogue/src/hypernet/graph.rs

```
| pub fn broadcast(&mut self, inp: Wire, to_shape: &[u64]) -> Result<Wire, BuildRefusal>
```

construction — crates/mtk-catalogue/tests/golden\_hypernet.rs

```
| let bc = b.broadcast(r, &[3, 2]).unwrap();
```

### 10.2.3 Structural plumbing: copy, delete, swap

**copy** duplicates one wire into  $k$  wires of the same type. Under linearity it is the only way a value acquires multiple consumers, so sharing is always a visible row — when the cartpole example of section 10.5 uses the pole-angle sine in three monomials, the graph says so with a single ternary copy.

**copy**

Primitive Catalogue entry H-COPY

The row (Computer Science Metanotation)

$$\frac{k \geq 1}{\text{copy}_k: \langle s, \delta \rangle \rightarrow \langle s, \delta \rangle^k} \text{ copy}$$

Semantics:  $\text{out}_i = \text{in}$  for every branch. Tag 6; under linearity, the only way a value acquires a second consumer.

## API

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

**TypeScript** hypernet.Builder.copy

signature — ts/src/hypernet.ts

```
| copy(inp: Wire, k: number): Result<ReadonlyArray<Wire>, BuildRefusal>
```

construction — ts/tests/hypernet-native.test.ts

```
| const ys = hn.unwrap(b.copy(y, 2));
```

**Rust** mtk\_catalogue::hypernet::HypernetBuilder::copy

signature — crates/mtk-catalogue/src/hypernet/graph.rs

```
| pub fn copy(&mut self, inp: Wire, k: u32) -> Result<Vec<Wire>, BuildRefusal>
```

construction — crates/mtk-catalogue/tests/golden\_hypernet.rs

```
| let ys = b.copy(y, 2).unwrap();
```

**delete** consumes one wire and produces nothing. A value nobody reads must be discarded by a row, never dropped by omission; the substitution operation of section 10.6 leans on this (“the discard is a row, never an absence”) when it repairs the seam between two graphs.

**delete**

Primitive Catalogue entry H-DELETE

**The row (Computer Science Metanotation)**

$$\frac{}{\text{delete}: \langle s, \delta \rangle \rightarrow \emptyset} \text{ delete}$$

Semantics: no outputs; the input's consumption is the entire content. Tag 7.

**API**

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

**TypeScript** `hypernet.Builder.delete`signature — `ts/src/hypernet.ts`

```
| delete(inp: Wire): Result<undefined, BuildRefusal>
```

construction — `ts/tests/hypernet-native.test.ts`

```
| hn.unwrap(b.delete(cells[0]));
```

**Rust** `mtk_catalogue::hypernet::HypernetBuilder::delete`signature — `crates/mtk-catalogue/src/hypernet/graph.rs`

```
| pub fn delete(&mut self, inp: Wire) -> Result<(), BuildRefusal>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
| b.delete(cells[0]).unwrap();
```

**swap** exchanges two wires, of possibly different types. It is the symmetry of the monoidal structure as an explicit application — pure renaming, no computation — so that wire order, like sharing and discarding, is syntax rather than convention.

**swap**

Primitive Catalogue entry H-SWAP

**The row (Computer Science Metanotation)**

$$\frac{}{\text{swap}: \tau_1, \tau_2 \rightarrow \tau_2, \tau_1} \text{ swap}$$

Semantics:  $(\text{out}_1, \text{out}_2) = (\text{in}_2, \text{in}_1)$  — pure renaming, types possibly distinct. Tag 8.**API**

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

**TypeScript** `hypernet.Builder.swap`signature — `ts/src/hypernet.ts`

```
| swap(in1: Wire, in2: Wire): Result<readonly [Wire, Wire], BuildRefusal>
```

construction — `ts/tests/hypernet-native.test.ts`

```
| const [s1, s2] = hn.unwrap(b.swap(d, ys[0]!));
```

**Rust** `mtk_catalogue::hypernet::HypernetBuilder::swap`

signature — `crates/mtk-catalogue/src/hypernet/graph.rs`

```
| pub fn swap(&mut self, in1: Wire, in2: Wire) -> Result<(Wire, Wire), BuildRefusal>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
| let (s1, s2) = b.swap(d, ys[0]).unwrap();
```

### 10.2.4 Branching: `cell`

**cell** is the case-analysis box. Its payload is a simplicial complex  $K$  in ambient dimension  $d$ : exact-rational vertex coordinates, a downward-closed and conformal list of simplices, and a list of *cells*, each a pair  $(S, F)$  of a simplex  $S$  and a proper subset  $F \subsetneq S$  of its vertices (the *extension set*). A point  $x \in \mathbb{Q}^d$  lies in the cell  $(S, F)$  when  $x$  is an affine combination  $x = \sum_{v \in S} \lambda_v v$  with  $\sum_v \lambda_v = 1$ ,  $\lambda_v \geq 0$  on the core vertices  $S \setminus F$ , and  $\lambda_v \leq 0$  on  $F$ . With  $F = \emptyset$  this is the closed simplex itself; each extension vertex opens the region outward through the facet opposite it. The sign split of the line — the instance that gates a ReLU below — takes the path complex with vertices  $-1, 0, 1$ : the cell pairing the edge  $[0, 1]$  with extension set  $\{1\}$  covers the nonpositive half-line, the cell pairing  $[-1, 0]$  with  $\{-1\}$  covers the nonnegative half-line, and the two overlap only at the origin.

The box’s typing: input one wire  $\langle [d], \mathbb{Q} \rangle$  — a point of the ambient space — and output one Boolean scalar per listed cell. Its semantics: the outputs are one-hot, with the hot output naming a cell that contains the input point. Where the point lies in several cells at once — on a shared boundary — *any* of the containing cells is an admissible choice. The hypernet’s semantics at such a point is the set of behaviours under all admissible choices; a rule or certificate that cites a `cell` output must hold under every one of them, and the reference evaluator’s tie-break (lowest cell index, documented as such) is a pinned representative, not a semantic commitment. Boundary nondeterminism is thereby owned by the proof obligations, not hidden in an evaluator convention.

One box in this role is a deliberate economy. A ReLU is copy, then `cell` over the sign split of the line (two cells: nonnegative and nonpositive), then a gating contract of the indicator against the value; an argmax-style advisory head is one `cell` over the fan of dominance cones in difference coordinates. Piecewise structure of any shape enters through this single door, and “where could this computation branch?” is answerable by listing its `cell` applications.

**cell**

Primitive Catalogue entry H-CELL

The row (Computer Science Metanotation)

$$\frac{K \text{ a valid simplicial complex in ambient dimension } d \quad \text{with cells } (S_0, F_0), \dots, (S_{n-1}, F_{n-1})}{\text{cell}_K : \langle [d], \mathbb{Q} \rangle \rightarrow \mathbb{B}, \dots, \mathbb{B} \quad (n \text{ outputs})} \text{ cell}$$

Semantics: the outputs are one-hot; a hot index  $j$  is admissible exactly when the input point lies in cell  $(S_j, F_j)$ , and on a shared boundary *every* containing cell is admissible — the nondeterminism belongs to the proof obligations, never to an evaluator convention. Tag 3; the calculus’s only source of disjunction.

## API

Producer API of the `mtk` toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue’s first entry](#).

**TypeScript** `hypernet.Builder.cell`

signature — `ts/src/hypernet.ts`

```

cell(complexIdx: number, inp: Wire): Result<ReadOnlyArray<Wire>, BuildRefusal>

export interface SimpC {
  readonly ambDim: number;
  /** Vertex coordinates, `ambDim` exact rationals each. */
  readonly vertices: ReadOnlyArray<ReadOnlyArray<QLike>>;
  readonly simplices: ReadOnlyArray<ReadOnlyArray<number>>;
  readonly cells: ReadOnlyArray<SimpCCell>;
  readonly hint?: string;
}

```

construction — ts/tests/hypernet-native.test.ts

```
const cells = hn.unwrap(b.cell(sigma, p));
```

**Rust** mtk\_catalogue::hypernet::HypernetBuilder::cell

signature — crates/mtk-catalogue/src/hypernet/graph.rs

```
pub fn cell(&mut self, complex_idx: u32, inp: Wire) -> Result<Vec<Wire>, BuildRefusal>
```

construction — crates/mtk-catalogue/tests/golden\_hypernet.rs

```
let cells = b.cell(sigma, p).unwrap();
```

### 10.2.5 Fan-in: stack

**stack** takes  $k$  wires of one common type  $\langle s, \delta \rangle$  and produces a single wire of type  $\langle k::s, \delta \rangle$ , with semantics

$$\text{out}[i, \text{idx}] = \text{in}_i[\text{idx}], \quad i = 0, \dots, k-1.$$

It is copy's dual — fan-in as explicit structure, exactly as fan-out is explicit copy — and its characteristic idiom is the *sum*: to add wires  $u$  and  $v$ , stack them and contract the stacked wire against the all-ones vector,

$$u + v = \text{contract}(\text{stack}(u, v), 1_2),$$

binding the new leading axis. Subtraction is the same idiom with a  $[1, -1]$  sign vector, which keeps imported model weights byte-faithful: negation lives in a separate constant, never in a rewritten payload. **stack** adds no disjunction (its facts are entry equalities, structural like copy's), and it is the newest member of the calculus — the next section is the story of why it had to exist.

**stack**

Primitive Catalogue entry H-STACK

The row (Computer Science Metanotation)

$$\frac{k \geq 1 \quad \text{all inputs of one type } \langle s, \delta \rangle}{\text{stack}_k : \langle s, \delta \rangle^k \rightarrow \langle k::s, \delta \rangle} \text{ stack}$$

Semantics:  $\text{out}[i, \text{idx}] = \text{in}_i[\text{idx}]$ . Tag 9; copy's dual, and the  $\Sigma\Pi$  boundary's visible seam.

## API

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

**TypeScript** hypernet.Builder.stack

signature — ts/src/hypernet.ts

```
stack(inputs: ReadOnlyArray<Wire>): Result<Wire, BuildRefusal>
```

construction — ts/tests/hypernet-native.test.ts

```
| const t = hn.unwrap(b.stack([s1, s2, ys[1!]!]));
```

**Rust** `mtk_catalogue::hypernet::HypernetBuilder::stack`

signature — `crates/mtk-catalogue/src/hypernet/graph.rs`

```
| pub fn stack(&mut self, inputs: &[Wire]) -> Result<Wire, BuildRefusal>
```

construction — `crates/mtk-catalogue/tests/golden_hypernet.rs`

```
| let t = b.stack(&[s1, s2, ys[1]]).unwrap();
```

## 10.3 Why ten: a completion theorem

The calculus was not designed to have ten boxes. It had nine — `stack` was absent — until compiling real networks forced the question of what the nine could not say, and the answer turned out to be a theorem rather than an inconvenience.

**Proposition 10.3** (the packing gap). *In the nine-box fragment (without `stack`), no wire can carry the sum of two independently produced wires: for any two wires  $u, v$ , no later wire has an entry whose expansion — read with  $u$  and  $v$  as opaque sources, whatever produced them — contains both a monomial with  $u$ -factors but no  $v$ -factors and a monomial with  $v$ -factors but no  $u$ -factors; in particular, no entry expands to  $u + v$  itself.<sup>3</sup>*

*Proof sketch.* Only `contract` combines values from more than one data wire — `cast`, `cell`, `reshape`, `broadcast`, `copy`, and `delete` are single-input, `const` is zero-input, and `swap` is a renaming. But every output entry of a `contract` is a sum of monomials each containing a factor from *every* input wire (Definition 10.2: the product runs over all  $m$ ) — the box is purely multiplicative across wires, and a constant input multiplies into every term rather than adding. So the first application to consume both  $u$  and  $v$  already violates the required shape, and single-input boxes only relabel or duplicate entries thereafter; induction along the SSA order closes the argument.  $\square$

The practical blast radius of this small proposition was total: no bias can be added to a linear layer ( $x - 1$  is already inexpressible), and after a ReLU layer splits into per-scalar gate indicators, nothing can reassemble the gated values into the next layer’s input — so no network with two or more neurons could be expressed at all, even though each individual matrix product and each individual ReLU could. Of the two sub-gaps, one (additive constants) admitted a workaround — an augmented-input convention carrying a constant-one component — at the price of an interface wart; the other (cross-wire packing of independently produced values) admitted none.

The repair is the tenth box. `stack` closes both gaps at once: sums become the `stack-and-ones` idiom of section 10.2.5, gate vectors assemble from per-scalar `cell` outputs, and with it every piecewise-polynomial dataflow — every ReLU network included — becomes expressible. Alternatives were weighed and declined: a vectorized `cell` (fixes gates, not bias, and complicates the format); a polynomial node promoted to primitive rank (collapses the `einsum` discipline — section 10.5 explains why the polynomial belongs at the view layer instead); a `contract` variant that also sums over a choice index (semantically equivalent to `stack-then-contract`, but it muddies the `einsum` reading, whereas `stack` keeps *product* and *sum* orthogonal). `stack` entered the calculus the same day the gap was written down.

Two properties of the repair deserve the emphasis of a design principle. First, `stack` introduces no new disjunction — the invariant that `cell` is the calculus’s only branching source survives the extension untouched. Second, the division of labour it induces is legible in compiled graphs: products form at `contract` boxes, cross-wire sums form at `stack-plus-ones` boxes, and the boundary between the  $\Sigma$  and the  $\Pi$  of a polynomial is a visible seam in the graph. The worked example of the next section shows that seam carrying exactly one `stack`.

What the ten boxes still deliberately cannot say, so that no reader over-extrapolates the completion: there is no transcendental function box, and there is no division box. An oscillator enters through the standard cylinder lift — carry  $s = \sin \theta$  and  $c = \cos \theta$  as state variables with the algebraic invariant  $s^2 + c^2 = 1$  —

<sup>3</sup>The expansion stratum, not run-time values, is where the claim holds at this generality: two `copy` descendants of one wire are produced by distinct applications, yet twice their common value is one `contract` against a constant. Read over expansions with  $u$  and  $v$  held opaque, the statement needs no independence hypothesis at all, and that is the form the mechanization proves (section 10.9).

rather than through a sin node; a rational right-hand side clears its mass matrix into implicit polynomial form. Both exclusions keep the genus inside piecewise-polynomial dataflow over  $\mathbb{Q}$ , which is where exact certification machinery has traction. The exclusion is a fact about boxes, not about reach: the admissible-symbol discipline of section 10.5 extends to a register of *certified function aliases* through which sine and cosine, rational powers, logarithm, and exponential become available anyway — as piecewise-polynomial approximations with declared domains and accuracy budgets, receipt-checked in exact rational arithmetic — without the wire format ever learning their names. Should a modelling frame ever genuinely force a quotient node, the procedural path is the one stack took: a written inexpressibility finding, an explicit decision, and enactment at the calculus layer — never a side-channel evaluator bolted onto a view.

## 10.4 Plates: symbolic extents

Token-population systems — coloured Petri nets first among them (section 12.18) — have variable-dimensional state: the number of tokens changes as the system runs, and is canonically unbounded across a run even though it is finite at every instant. A certificate about such a system is a function on markings — multisets of token colours — and a naive syntax would need one computation graph per token count: a countable family of artefacts where one certificate was wanted. The calculus closes this gap with *plates*: symbolic extents, not an eleventh box.

**The data.** Two additions to Definition 10.1, both container-level. The container gains an ordered finite list of *plate variables*  $\iota_1, \dots, \iota_r$  (serialized de Bruijn by position; debug names excluded from canon, like wire names). And the extent alphabet in wire shapes and contraction-pattern index extents becomes  $E ::= n \mid \iota$  — a literal or a declared plate variable, with no extent arithmetic ( $\iota + 1$  is not an extent; products of plates arise as multiple axes on one wire, never as extent products). A *plated hypernet* is the same record over the extended alphabet plus the plate list; a plated hypernet with zero plates is a hypernet, byte for byte. For an extent assignment  $\sigma : \{\iota_1, \dots, \iota_r\} \rightarrow \mathbb{N}$ , *instantiation*  $\text{inst}_\sigma$  replaces every symbolic extent by its value, yielding an ordinary hypernet; everything downstream — evaluator, canonical serialization, the whole checker stack — consumes instances and only instances. The plate is marked on *wires* (a per-token scalar is a wire of shape  $[\iota]$ ; a token family of  $d$ -dimensional colours,  $[\iota, d]$ ; an attention matrix,  $[\iota, \iota]$ ), never as a membrane around a subgraph: scope would be degenerate — plate variables are container-level — and what a membrane would add beyond axes is per-index variation of the body, which is exactly what the equivariance theorem below must forbid.

**How the boxes lift.** One principle, ten instances: a box lifts along plate axes by whiskering — the lifted application is the original box applied per index tuple, well-typed exactly when the box’s typing clause holds over the extended alphabet, with extent equality read *syntactically* (literal against literal numerically;  $\iota$  against  $\iota$  by name; a  $\iota$ -against-literal match is refused — conservative, never unsound, since schematic typing must hold at every  $\sigma$ ). *contract* admits symbolic index extents (a bound symbolic index is a pool over the instance’s extent; a free one maps over it); *broadcast* may add or extend plate axes under the trailing-axis rule, the membrane-crossing law in wire clothing (a plate-free wire broadcast along  $\iota$  is constant along the index); *cast*, *copy*, *delete*, *swap* are pointwise; *stack* keeps literal arity (a plate-sized family is never  $\iota$  separate wires — it is one wire carrying the  $\iota$  axis, from birth); *reshape* is refused on symbolic-extent wires in this edition (symbolic *totalSize* equality is decidable polynomial identity, but *contract* carries the demand natively, so nothing routes through it); and *const* — the load-bearing refusal — takes all-literal shapes only, forced rather than chosen: a literal tensor has finitely many entries.

**Three theorems, nearly free from one syntactic fact.** The language has no token literals: no expression for “the  $i$ -th token,” no order or successor on the index sort, no per-index branching (a *cell* reads colours, never indices), and *const* cannot utter a plate. Three consequences make the notation functorial rather than decorative.

- **Schematic well-formedness.** A well-formed plated hypernet instantiates to a well-formed ordinary hypernet at *every* extent assignment: instantiation is a homomorphism on extents, every typing clause is syntactic extent equality plus extent-free conditions, and both survive substitution.

- **Equivariance for free.** The instance family is natural in bijections of each plate’s index set: every expressible plated computation is equivariant under the product of symmetric groups, *as a theorem of the grammar* rather than a proof obligation on artefacts — plate axes are born only from the interface, broadcast, and contract, all equivariant, and the mutant that adds an index-literal box breaks the theorem at a two-token transposition, kernel-visibly. A corollary worth the emphasis: *causal masking is unwritable*. A causal mask is a function of the index order, and the syntax has no order to consult — the transformer this calculus can express is inherently the exchangeable one.
- **Descent.** An output wire carrying no plate axis is invariant, hence descends to the multiset quotient: the family assembles into one function on the bag space  $\bigsqcup_{n < \omega} \text{Sym}^n(B)$  — with one plate per place, precisely the coloured-net marking space of section 12.18. One finite syntax object denotes a function of the whole variable-dimensional state.

Semantically the plate is a functorial box in the sense of Melliès [178] — the strong monoidal functor  $(-)^{\otimes I}$ , drawn as axes instead of a membrane — and at infinite index it is the plate over a Kolmogorov product in the sense of categorical probability [43], the unique morphism whose finite marginals are the body’s instances. The index category is deliberately the groupoid of finite sets and bijections, not all functions: aggregation is not functorial under instance insertions [222], and equivariance is exactly the functoriality that survives — which is the symmetry the marking space quotients by.

**The count wire.** The const refusal bans  $\iota$  in a literal’s *shape*, never the scalar. So the token count is three applications — const 1, broadcast to  $[\iota]$  (the vacuous instance of the trailing-axis rule), contract binding the index — and each instance evaluates to  $n$ . Uncoloured counter places need nothing else: classical place-invariant certificates are degree-one polynomials in count wires, and count-bound rows ( $0 \leq k_P \leq M_P$ , linear conservation laws) attach to this wire. The idiom is a natural packaged symbol for the register of section 10.5 — expansion as above, projection lemma trivial — so certificates may cite one symbol while the wire format never learns it exists.

**The certificate stratum never sees a plate.** A plated hypernet with invariant outputs, built from contract pools, is a presentation of an aggregate polynomial in finitely many *pooled coordinates*: token counts  $\vec{k}$  and per-place power-sum pools  $\vec{s}$  (a sum-pool is a contraction row whose bound index is the plate — the relational rendering of section 10.8 applies unchanged, side conditions included). Obligations about all markings at once are ordinary polynomial sequents over  $(\vec{k}, \vec{s})$  with hypothesis rows — coupling enclosures  $l_j k_P \leq s_j^P \leq u_j k_P$  from the colour boxes, count rows, integer rounding at count atoms — so obligation count and dimension are set by the net and the feature dictionary, never by any marking bound. The plate joins “the checker never sees a probability” and “never sees a marking”: it compiles away through the pooled normal form, and what reaches the kernel is hypothesis-carrying polynomial rows of the standard shape. How the per-transition rows of a token-population system collapse to one row per Petri transition — and which pooled aggregators can carry progress claims, not merely safety — is taken up with the modelling frame itself (section 12.18).

**Worked size.** A one-layer transformer encoder with degree-2 polynomial attention — a published, empirically competitive attention class [159], of which the plate-expressible fragment is precisely the exchangeable subclass — over a two-dimensional colour box, with residual connection, invariant quadratic readout, and count wire, is *nineteen applications*, of which the count wire is three; its pooled normal form is a per-token quadratic form against pooled third moments, an aggregate polynomial over fifteen pool coordinates plus the count. An executable exact-rational fixture pins the transcription against a per-token symbolic computation at  $n \in \{1, 2, 3\}$ , the collapse identity symbolically, and invariance under all  $n!$  permutations.

**Status.** The type layer and the three theorems are mechanized in the Lean catalogue (lean/qts1, modules Qts1/Plate/{Syntax, TPlate, Eval, TNat, TDesc, Probes}): symbolic shapes and their instantiation homomorphism, the lifted per-box typing table with the schematic well-formedness theorem across all ten boxes, a reference evaluator with the diagonal-action equivariance theorem, the unwritability of causal masking (stated as a refutation: the one-application index-literal extension falsifies equivariance at  $n = 2$ ), descent to Multiset-indexed denotations, and a symbolic count-wire evaluation theorem, under a three-mutant battery at preregistered loci. The certificate-stratum row family this section’s pooled normal

form calls for — plate declarations, per-token feature dictionaries, aggregate wires as contraction rows, fold certificates with per-transition footprint rows, and the idempotent-gap refusal — is landed theory vocabulary, and the producer emits it: the semiconductor tutorial (chapter 17, section 17.5) is its first exercising campaign, and the engine-side evaluator family for the theory's demanded side conditions now discharges them in that campaign's production loop, decided at the coloured place/transition fragment with the remainder refused by name (section 17.5.8). The hypernet *wire-format* extent tag itself — symbolic extents on general wires, beyond the certificate rows — remains design with its pieces priced; plate-free serialization is unaffected by construction (zero-plate graphs are byte-identical today).

## 10.5 One genus: views elaborate in

A toolkit that certifies computations cannot afford two kinds of computation. The design rule entered the development log as a maxim the day the System layer adopted hypernets for its dynamical content: hypernets are to be re-used for differential-equation specifications and their kin. The maxim had an edge because the project had already lived through the failure once, when terms grew into a separate genus from hypernets and were soon demanding einsum machinery of their own.

The rule this chapter takes from that entry, stated positively:

**The single-genus rule.** Hypernets are the one genus of computational content. Every other computational syntax — a polynomial vector field written as a coefficient table, a term inside a proof obligation, a guard expression, a PDE operator — is a *view*: surface syntax equipped with a definitional elaboration into the ten boxes. A view's meaning *is* the value of its elaboration; no view acquires its own evaluator, its own serialization, or its own contraction machinery.

The precedent for the pattern is einsum itself. Einsum notation is not a second contraction engine anywhere in the toolkit; it lowers to explicit contraction structure (patterns here; contraction rows in the relational engine, section 10.8), and the summation it denotes is definitional — evaluated only where a checker needs values. Views generalize this: convenient syntax on the outside, one calculus on the inside, and the translation is part of the definition rather than an implementation detail.

The disease the rule prevents has a concrete signature, worth naming because it is how single-genus erodes in practice: a producer grows an ergonomic node — say, a polynomial represented as its monomial table — that is not among the ten boxes; artefacts begin to carry it *instead of* applications; and some downstream consumer, finding no applications to read, grows an evaluator against the ergonomic node directly. At that moment there are two genera, two evaluators, and a fresh supply of questions about whether they agree. The repair — performed on the polynomial node itself, and now the standing template — is *demotion to view* under the admissible-symbol discipline:

- an **admissible packaged symbol** is a named node with a typing rule, admitted alongside (never into) the core ten;
- it carries a **definitional expansion** into core boxes — the node *serializes as* its expansion, so the wire format and the digest scheme never learn the symbol exists;
- a once-proven **projection lemma** establishes that the symbol's declared facts follow from its expansion's facts, so rules may cite the symbol soundly;
- and a **candidacy rule** bounds the admission: the expansion's disjunctive content must come only from `cell` (most packaged symbols are disjunction-free; a packaged ReLU inherits its single case split from the `cell` inside its expansion, and nothing else is allowed to smuggle new branching into the calculus).

Four packaged symbols currently ride this register, each with its expansion and projection lemma mechanized: `relu` (expansion: copy, sign-split `cell`, gating contract); `ppoly`, the monomial-table polynomial view whose expansion is the scheme of the worked example below; `pderiv`, the formal partial derivative on dense coefficient tables (expansion: one constant shift-and-scale matrix and one contract); and `facet`, restriction of a coefficient table to a face (expansion: one basis-vector constant and one contract). None is an eleventh primitive; all four erase at serialization time.

Three audit questions probe any proposed addition, and the calculus answers all three by construction: *a second evaluator?* — no; views elaborate, and the one exact evaluator computes. *A second digest scheme?* — no; the canonical serialization hashes expansions, so a view and its elaboration cannot drift apart behind distinct content addresses. *A second contraction path?* — no; the contraction pattern is the only index-binding construct, and any syntax “asking for its own einsum” is asking, by definition, to violate the rule.

## Beyond exactness: certified function aliases

One register remains, opened by a question the packaged symbols cannot answer. Modelling frames keep asking for  $\sin$ ,  $\cos$ ,  $t^{p/q}$ ,  $\ln$ , and  $\exp$  — in drift coefficients, rate laws, guard surfaces — and no piecewise polynomial *equals* any of them, so no definitional expansion of the packaged-symbol kind can exist. What can exist, and what exact numerics has shipped for decades under the name of certified function libraries [185], is an approximation with a proof: a piecewise-polynomial table  $\hat{f}$  over exact rationals, a declared domain  $[a, b]$ , and a declared budget  $\varepsilon$ , together with a receipt — exact-rational inequalities a small checker re-derives from the table bytes alone — establishing  $|\hat{f} - f| \leq \varepsilon$  on the domain. Remainder brackets of the Maclaurin kind make such receipts pure rational arithmetic (the checker compares coefficients against a factorial tail bound; it never needs to know that  $e$  exists), and implicit relations extend the same discipline to functions the brackets do not reach directly: a logarithm table is certified through the residual  $|\exp(\hat{w}(t)) - t| \leq \eta t$  against exponential brackets, a rational-power table through the purely polynomial residual  $|\hat{w}^q - t^p| \leq \eta$  — so no logarithm and no fractional power is ever enclosed by anything but polynomial comparison.

A *certified function alias* packages exactly this: a name and pinned parameters selecting one table, hence one hypernet (the pieces enter through `cell`, the piece polynomials through the `poly` scheme, the one-hot blend through `contract`); the budget  $(\varepsilon; [a, b])$ ; and the receipt's citation. The alias is admitted alongside the calculus in the same sense as the packaged symbols — the wire format and the digest scheme never learn its name; artefacts carry the expansion — and the three audit questions above pass by the same erasure argument. What changes is the epistemic contract: a packaged symbol's projection lemma says *equal*; an alias's receipt says *within  $\varepsilon$ , on  $[a, b]$*  — and the domain is a precondition, owed a containment argument by any consumer whose wires might leave it, the same obligation shape as a jump's reset containment. Downstream, the distinction costs nothing; a drift built from an alias *is* piecewise-polynomial dataflow, its proof obligations are polynomial rows like any other, and the transcendental fact lives entirely in the receipt. A claim over such a system may then be read at either of two strengths: against the table as the model itself, with  $\varepsilon$  a declared modelling tolerance of the same kind as float rounding (the reading under which nothing downstream changes at all); or against the band  $\hat{f} \pm \varepsilon$  as a differential inclusion, whose verdict covers the true function by containment at the price of one rational widening term per obligation row.

The family is closed under differentiation —  $\sin' = \cos$ ,  $\exp' = \exp$ ,  $\ln' = t^{-1}$ ,  $(t^{p/q})' = \frac{p}{q} t^{p/q-1}$  — so an alias's derivative data is a pointer to a sibling alias, never new machinery. The cylinder lift met earlier in this chapter remains the better encoding where it applies (an autonomous oscillator's sine and cosine carried as state, exactly, with their algebraic invariant); the alias route serves the cases the lift cannot reach — forced and parametric arguments, logarithms and powers of state variables, rate laws. The toolkit carries certified tables for the whole family named above. The exponential, the logarithm, and the rational powers arrived first, as quantile transforms for its distribution generators, verified by the residual disciplines above; sine and cosine followed as forward tables on a declared symmetric domain, their error bounded absolutely against the same factorial-tail brackets the remainder arguments above consume — absolutely of necessity, since both functions vanish inside every interesting domain, leaving a relative bound no positive floor to stand on. One more fact about the trigonometric pair is worth the ink:  $\pi$  is irrational, so periodic folding is not exactly available in  $\mathbb{Q}$ , and a range-reduced table would smuggle an approximation of  $\pi$  into its own argument, outside the certificate. The declared domain is therefore data; coverage beyond it is refused, never clamped, and range reduction is the consumer's burden, priced where the consumer knows its own modulus.

Figure 10.1: The closed-loop cartpole drift of the worked example, depicted as a hypernet: fifteen applications, three inputs, three outputs. Structural plumbing (copy, grey) makes every act of sharing a visible row; constants (white) are applications like everything else; every monomial is one contract (peach); and the calculus’s single cross-wire sum — the three-term right-hand side of  $\dot{\omega}$  — crosses the  $\Sigma\Pi$  boundary (dashed) as one stack contracted against the all-ones vector.

### Worked example: a closed-loop drift, in fifteen applications

The example that carried the design discussion is small enough to print whole. Take the cartpole’s closed loop on the cylinder lift  $(s, c, \omega)$  — sine and cosine of the pole angle carried as state, per the no-transcendentals discipline — with a linear feedback law  $a(s, \omega) = K_0 s + K_1 \omega$  folded in, plant half-length  $l = \frac{1}{2}$ , gravity  $g = \frac{49}{5}$ , and exact rational gains  $K_0 = -\frac{161753}{8148}$ ,  $K_1 = -\frac{44746}{9799}$ :

$$\dot{s} = c\omega, \quad \dot{c} = -s\omega, \quad \dot{\omega} = \frac{g}{l}s + \frac{K_0}{l}cs + \frac{K_1}{l}c\omega.$$

Its hypernet — three input wires, three output wires, every scalar a rank-0 exact rational — is fifteen applications:

| stage                    | applications                                                                          | count |
|--------------------------|---------------------------------------------------------------------------------------|-------|
| fan-out                  | copy each of $s, c, \omega$ into its uses                                             | 3     |
| constants                | const $-1, \frac{g}{l}, \frac{K_0}{l}, \frac{K_1}{l}, 1_3$                            | 5     |
| monomials                | contract: $c\omega; (-1)s\omega; \frac{g}{l}s; \frac{K_0}{l}cs; \frac{K_1}{l}c\omega$ | 5     |
| the $\Sigma\Pi$ boundary | stack the three $\dot{\omega}$ monomials into shape $[3]$                             | 1     |
| the sum                  | contract against $1_3$ , binding the $[3]$ axis                                       | 1     |

Every monomial is contract-native; the single cross-wire sum in the system — the three-term right-hand side of  $\dot{\omega}$  — is the single stack (Figure 10.1). The table is not hand-lore: the polynomial view elaborator emits this graph, its fifteen applications digest to a pinned golden (69b6f4c6...), and the elaborator’s output is already in canonical form, so the digest doubles as a regression witness for the elaboration itself. Neither is the figure hand-lore: it is emitted, deterministically, from those same canonical bytes by the depiction tool beside the producer surface (hypernet-tikz), so the pinned digest is the drawing’s witness too — only the semantic names ( $s, c, \omega, g/l$ ) arrive as declared labels, since the canonical form deliberately carries no name metadata. The same scheme compiles the goal polynomial of the matching Lyapunov certificate — one more stack, one more ones-contract — which is the single-genus rule doing exactly its job: system dynamics and certificate content share one representation, so one recomputation can cross-check a digest cited by both.

## 10.6 Substitution: how hypernets compose

Hypernets compose by *substitution*: plugging one graph’s outputs into another’s inputs. The operation is defined once, at the graph layer, and everything that composes computations — nesting a component’s

dynamics inside a larger mechanism, elaborating a view in context, merging two boxed computations into one — consumes the same definition.

The data of a substitution: an outer hypernet, an inner hypernet, a *port map*  $\varphi$  matching some of the outer graph’s inputs to inner outputs (type-exact; several outer inputs may consume one inner output), and an *exposure set* of inner outputs to remain outputs of the composite — by default the unmatched ones, so nothing is silently dropped and nothing matched is silently re-exposed. The construction concatenates the inner application list, a block of *seam repairs*, and the redirected outer list, then rennumbers into canonical form. The seam repairs are where the linearity discipline pays: an inner output consumed by  $n$  ports and exposures gains exactly one consumer at the seam — a *delete* when  $n = 0$  (the discard is a row, never an absence), nothing when  $n = 1$ , a *copy* when  $n \geq 2$  — and consumer counts change nowhere else.

**Theorem 10.4** (substitution laws). *For well-formed hypernets and valid port structures: (i) the composite is well-formed; (ii) on the deterministic fragment, evaluation of the composite equals the composition of evaluations — inner outputs feeding matched outer inputs, unmatched interface passing through; (iii) substitution is unital (substituting an identity hypernet, in either direction, returns the other graph up to canonical renumbering) and associative — and both laws hold on the nose for the canonical forms, hence as equalities of digests, not merely up to isomorphism.*

The proofs are elementary but not careless; the one choice that genuinely matters is *where the repair blocks live*. Placing each seam’s repairs at that seam — between the inner and outer blocks it mediates — makes the two association orders of a three-graph chain produce byte-identical canonical forms; the tempting alternative (all repairs at the end) satisfies (i) and (ii) equally well and breaks (iii) at the digest layer, leaving associativity only up to a permutation that content-addressing does not forgive. Coherence at the byte level is a design property, chosen because certificates compare bytes.

Clause (ii) as stated is a floor, and the machine-checked form is stronger. In the toolkit’s Lean tree, composition at the aligned stratum — the pushout-normal form in which the seam wires of two composable open hypernets are literally shared names, the form every composite of content-addressed hypernets reduces to — carries the law family with no determinism hypothesis anywhere (module `Qtsl.HypernetCospan`): gluing preserves well-formedness wholesale — linearity, acyclicity, type consistency, and every boundary clause (`glue`); a valuation of the composite is admissible exactly when every application of each part holds (`glue_admissible_iff`); and unit and associativity hold on the nose (`glue_unit_left`, `glue_unit_right`, `glue_assoc`) — clause (iii)’s shadow in pushout-normal form.

The relational law subsumes the deterministic clause: where the parts’ admissible relations are graphs of functions, “every application holds” is exactly “evaluation of the composite equals the composition of evaluations” — and `cell`’s one-hot disjunction, the calculus’s one nondeterministic citizen, passes through the conjunction untouched. The composition law never needed determinism; clause (ii) names the fragment where “evaluation” is a function because that is the fragment the evaluator runs.

Read through that normal form, the seam repairs acquire a precise status: they are a *change of interface*, never composition overhead. The bridge between the two presentations is itself machine-checked (module `Qtsl.SubstitutionBridge`): substitution factors as a gluing against a small structural hypernet — one *delete* or *copy* row per seam wire whose consumer count changes — that mediates between the inner graph’s interface and the interface the port map asks for, and the seam-repair block is that mediator’s application list, verbatim. Gluing along an interface both sides already agree on inserts nothing; the rows appear exactly when the interface moves.

For certificate consumers, the digest story splits into three claims of different strengths, and keeping them separate is what makes “digest coherence” a tool rather than folklore:

**Remark 10.5** (digest verdicts). *(a) Determination — a theorem.* The composite’s digest is a function of the parts’ canonical bytes and the port structure: the operation reads nothing else. Equal-digest parts yield an equal-digest composite, so a certificate may cite the parts and the port row and thereby pin the whole. *(b) Coherence — a theorem, conditional on a discipline.* The unit and associativity equalities of Theorem 10.4(iii) are digest equalities *because* normalization is part of the operation; producers must emit canonical form or normalize before digesting, and the elaborators do (their outputs are fixed points of renumbering, checked). *(c) Homomorphism — refused.* There is no operation on digest *strings* computing the composite’s digest from the parts’ digests: SHA-256 composes with nothing, by design. The checker’s path is recomputation —

possess the parts' bytes, recompute the substitution, compare the claimed digest — and every consumer in the toolkit uses that pattern rather than assuming an algebra of hashes.

One boundary deserves stating before anything leans on it: elaboration and substitution commute *semantically* (elaborating a polynomial composite equals substituting the elaborations, as functions; proven, with executable witnesses), but the two routes produce *different graphs*, and different graphs never share a digest. Expanding a polynomial before elaborating re-associates its monomials; substituting factored graphs keeps the factoring. A certificate relating the two routes therefore carries a semantic linkage argument, never a claimed hash equality — the digest refuses extensionality on purpose, and this is the first place the refusal does real work.

## substitution

Primitive Catalogue entry H-SUBST

### The row (Computer Science Metanotation)

$$\frac{G, H \text{ well-formed} \quad \varphi: \text{in}(G) \rightarrow \text{out}(H) \text{ type-exact} \quad E \subseteq \text{out}(H) \text{ (default: the unmatched outputs)}}{\text{subst}(G, \varphi, H, E): \text{in}(H) + (\text{in}(G) \setminus \text{dom } \varphi) \rightarrow \text{out}(G) + E} \text{ SUBST}$$

Semantics and laws: Theorem 10.4 — composition of evaluations on the deterministic fragment; unit and associativity on the nose, as digest equalities. The seam repair is forced by linearity: an inner output with  $n$  consumers at the seam gains a delete ( $n = 0$ ), nothing ( $n = 1$ ), or a copy ( $n \geq 2$ ), and consumer counts change nowhere else. The operation normalizes its result (the canonical renumbering); the identity hypernet is its unit.

## API

Producer API of the mtk toolkit — the TypeScript arrangement and the Rust catalogue crate, one implementation underneath. The extraction, corpus, and receipt disciplines governing this block are stated once, at [this catalogue's first entry](#).

The normal form (renumber) and the unit (the identity hypernet) are quoted alongside `substitute`. The corpus construction exercises a fan-out seam, a delete seam, an explicit exposure, and a pass-through port; the composite's bytes are verified against the reference operation's output.

### TypeScript `hypernet.substitute`

signature — `ts/src/hypernet.ts`

```
export function substitute(
  outer: Hypernet,
  portMap:

let comp = substitute(&outer, &port_map, &inner, Some(&expose), true).unwrap();

```

## 10.7 The shared core: Systems, specifications, rules

The claim this chapter exists to underwrite: the three strata that consume computation all consume *this* genus, so the chapter’s material is common infrastructure, not one stratum’s private concern.

### Systems: mechanism content is boxed hypernets

A System (chapter 12) is a structured presentation — mechanisms wired together — and the mechanism calculus itself deliberately contains *no computational primitives at all*. Its vocabulary identifies variables, grades stochastic couplings, sequences operating modes, nests components; none of these operations computes a value. Wherever a mechanism has dynamical content — a drift field, a jump reset, a guard, a neural feedback law — that content is a hypernet, referenced by digest.

The embedding has a precise grammar: a well-formed hypernet with  $m$  inputs and  $n$  outputs becomes a mechanism whose ports are its wire types and whose causal orientation is fixed (inputs consumed, outputs read out) — a *deterministic directional mechanism*, sitting inside the System layer as what string-diagram practice calls a functorial box [178]: a membrane with hypernet calculus inside and mechanism calculus outside. Composition respects the membrane — merging two boxes joined by a directed wire is computed by the substitution operation of section 10.6, inside — and the membrane is selective in both directions. Relational variable-identification, graded stochastic couplings, and mode-switching edges cannot cross into the box: they are not computations. Acyclicity ends at the membrane in the other direction: inside, SSA order is law; outside, feedback loops are the System layer’s bread and butter, closed through state across box boundaries. A control loop is a cycle of mechanisms whose every computational fragment is internally acyclic — which is how the toolkit gets both certified computation and real feedback without either discipline compromising the other. (In the vocabulary of Theorem 10.6 below: a functorial box packages a well-formed, deterministic loose arrow of the double category of open hypernets, and the membrane is that fragment’s boundary.)

### Specifications: one digest, one referent

A specification constrains observables of a trajectory; a certificate discharges the constraint with computational content of its own — a Lyapunov function’s polynomial, a barrier’s gradient bounds, the observable defining a guard surface. Both sides of that transaction are hypernets, and both cite digests under the one canonical serialization. The consequence is a sentence this book will rely on repeatedly, in both directions:

*the guard the certificate reasons about is the guard the system runs*, and the checker verifying the certificate can confirm as much by recomputing a hash — no semantic argument, no trusted translation step, no “the spec model and the implementation model surely agree.” Where a certificate’s content is produced by elaboration from a view, digest determination (Remark 10.5a) extends the same guarantee through the elaboration: cite the view’s parameters and the elaborator’s version, or cite the elaborated digest directly; either way the referent is pinned by content.

## Rules: the ambient hypernet

Every inference rule in the catalogue of chapter 15 is stated over an ambient hypernet: the rule’s variables are wires, its premises and conclusions constrain the values those wires can take, and its soundness theorem quantifies over *every* hypernet and every admissible valuation. The primitive boxes supply the base facts — each application contributes its defining equations (a contract’s sum-of-products identity, a stack’s entry equalities, a cell’s one-hot disjunction) as the synthesized facts rules build on. The economy of section 10.2 becomes a proof-theoretic economy here: nine box families contribute equations, exactly one contributes a disjunction, so case analysis in the rule layer is confined to cell-shaped splits, and a packaged symbol admitted under the candidacy rule of section 10.5 cannot enlarge that confinement.

This triple consumption is the chapter’s placement argument. Systems, specifications, and rules each depend on the hypernet genus; the genus depends on none of them. Read this chapter once, and the later chapters’ references — “dynamical content, by digest,” “the ambient hypernet,” “the certificate cites the graph” — resolve to one object with one definition.

The placement argument also has a mathematical face, and the face is machine-checked.

**Theorem 10.6** (possibilistic inclusion). *Open hypernets — hypernets with declared input and output rosters — form a double category: objects are wire rosters, tight arrows are roster inclusions, loose arrows are hypernet-decorated cospans in the sense of Fong [80], read at double-categorical strength through Patterson’s lens [193], and loose composition is gluing at the shared seam. Sending an open hypernet to its possibilistic content — the set of valuations its applications admit — extends to a lax double functor from this double category into the semantic universe of chapter 9, and the functor:*

1. *satisfies its unit, composition, and rename-transport laws as exact equalities, with no determinism hypothesis anywhere;*
2. *preserves the canonical opcartesian lifts on the nose;*
3. *has its composition comparison invertible precisely on seam-disjoint gluings — which is every gluing of encoded hypernets, since content addressing makes wire names rigid designators: distinct off-seam wires never collide, and no capture-avoiding renaming ever intervenes;*
4. *identifies two hypernets precisely when they admit the same valuations.*

Every clause is a named artefact in the toolkit’s Lean tree. The packaged functor is `hnetInclusion` (module `SuFunctor.HypernetDouble`), built from four transformation laws proved exactly, one by one, in `SuFunctor.HypernetInclusion`: unit, composition with no determinism hypothesis (section 10.6’s relational law is this clause read at the substitution seam), rename transport at full generality, and the vacuous-diagram law (`theta_unit`, `theta_comp`, `theta_rename`, `vacDnf_dnfPull`). Lift preservation is `hnetInclusion_pushGLoose`. The laxity is located, not hidden: clause 3 is `hnetInclusion_laxComp_isInvertible`, while the unit comparison is genuinely one-way — typing lives in the pattern carrier, and forgetting it is a constraint, not a defect. Clause 4 (`austereDnf_eq_iff`) says the inclusion is deliberately non-faithful, and makes its kernel a theorem rather than a folklore caveat: it is the extensionality refusal of section 10.1 standing exactly where it belongs — two graphs computing one relation share a meaning and never a digest; syntax and its content addressing live in the double category, and the semantic universe sees the relation.

What Systems, specifications, and rules consume is therefore not merely one data structure but one semantics: composing graphs and then taking meaning equals taking meaning and then composing relations.

## 10.8 Relational kinship: contraction rows

The toolkit meets tensor contraction twice: as the `contract` box here, and as *contraction rows* in the relational engine, where an `einsum` expression lowers to stored index structure — an index map and an output set as data — with the summation definitional, evaluated only where a checker needs values. The two are one definition at two strata, and it is worth seeing the shared skeleton once. Over a semiring  $\mathbb{S}$ , with a finite family of input axes  $A(i)$  and a map  $a$  from input-axis positions into a finite index set, contraction along  $a$  with output set  $O$  sends a (lazily formed) product tensor to

$$\left( v: \prod_{m \in O} B(m) \right) \mapsto \sum_{v': \prod_{j \notin O} B(j)} T(i \mapsto (v \cup v')(a(i))),$$

where the extent family  $B$  is induced on the image of  $a$  by the input extents, and is data only on the output axes no input hits (the broadcast axes, of which more below). Definition 10.2 is this formula with  $\mathbb{S} = \mathbb{Q}$ , the index set  $I$  playing the target of  $a$ , the input bindings playing  $a$ , and the output binding enumerating  $O$ ; the box evaluates it eagerly on wire values, the relational rendering stores it as rows and lets the checker fold the sum on demand. The design move is also shared: *einsum lowers to contraction rows* in the engine for the same reason *views elaborate into hypernets* here — surface notation is never given its own machinery.

Two deltas between the strata, stated so the kinship is not overclaimed. First, the relational side imposes a side condition the wire format does not: every index hit by no input must belong to the output set, so the case that would silently scale a result by an extent is *unrepresentable* in rows, while in the IR the same case is representable and simply carries its summed semantics — deterministic, if rarely what anyone meant; `einsum` lowerings never emit it on either side. Second, broadcasting: the relational rendering folds it into contraction itself (output axes hit by no input are the broadcast axes, along which the result is constant), while the IR keeps a separate broadcast box — in a dataflow graph the degenerate contraction would cost a pattern where a relabelling suffices. Same semantics; different economies; one calculus.

## 10.9 Receipts

What stands behind this chapter, sorted by strength of evidence, per the claim discipline used throughout the book.

**Machine-checked and running.** The ten-primitive calculus exists twice, in agreement: as a mechanized catalogue (the primitive type, per-box typing rules, and the well-formedness trio as decidable predicates over ground data, with well-formedness carried as proof fields of the hypernet structure) and as a reference implementation (the same typing and well-formedness checks, the exact- $\mathbb{Q}$  evaluator, a float64 shadow evaluator carrying a conservative accumulated-rounding bound, and the canonical serialization with SHA-256 digests). An ONNX importer compiles all 45 networks of the ACAS Xu collision-avoidance benchmark [134] (architecture 5–50×6–5, ReLU) to well-formed hypernets — 2,172 applications and 2,767 wires per network, exact dyadic weights — with committed digest goldens (45 networks × 3 head variants, all 135 distinct) and an oracle gate: on 47 published verification instances, exact and shadow evaluation agree within the carried bound (largest observed gap  $1.9 \times 10^{-16}$ ), and verdicts agree with an independent floating-point runtime 47/47. A property battery (well-formedness of random SSA slices; digest sensitivity — a one-ulp weight corruption flips the digest, a clean recompile reproduces the golden; evaluator agreement against an independent forward pass) runs green in seconds. The substitution operation and canonical renumbering are implemented, with the coherence and digest laws of section 10.6 each exercised by executable digest-equality witnesses (among them the deliberate digest-*inequality* of the two elaboration routes). The polynomial-view elaborator is pinned to the fifteen-application worked table by its committed digest golden, and the four packaged symbols' expansions live in the mechanized catalogue with their projection lemmas. The composition layer above the catalogue is machine-checked in the same tree: the aligned-stratum gluing with its relational law and on-the-nose unit and associativity (`Qtsl.HypernetCospan`), the reduction of the port-map substitution to that gluing (`Qtsl.SubstitutionBridge`), the four transformation laws of the possibilistic inclusion (`SuFunctor.HypernetInclusion`), and their packaging as a lax double functor into the semantic universe (`SuFunctor.HypernetDouble`) — sorry-free, axiom census the standard classical base. The plate extension (section 10.4) is machine-checked at the same grade in `Qtsl/Plate/{Syntax, TPlate, Eval, TNat, TDesc, Probes}`: symbolic shapes and instantiation, schematic well-formedness across all ten boxes, evaluator equivariance under the diagonal symmetric-group action, the causal-mask refutation,

descent to multiset-indexed denotations, and the symbolic count-wire theorem, under a three-mutant battery at preregistered loci (index-literal box, widened broadcast slot, deleted contract-binding clause — each refused at its predicted theorem); an exact-rational fixture additionally pins the nineteen-application polynomial transformer against per-token symbolic computation at  $n \in \{1, 2, 3\}$ .

**Proven in prose, with executable witnesses; mechanization under way.** Proposition 10.3 (the completion theorem behind stack) and Theorem 10.4 (well-formedness preservation, the merge law, unit and associativity on the nose) are proven at full detail in the development record’s design notes, and every claimed equality is additionally checked by the executable witnesses above. The proposition is, further, machine-checked in the toolkit’s Lean tree (lean/qtsl/, module Qtsl.PackingGap): a sorry-free Lean development, its axiom census the standard classical base, mechanizes it over the formal-expansion support model the proof sketch itself runs on — assuming no well-formedness, quantifying over all wires rather than only later ones, and holding the two tracked wires opaque whatever produced them — together with a positive control deriving the forbidden configuration once stack is added, so the nine-box hypothesis is itself proven necessary. Of Theorem 10.4 in the port-map presentation given here, the linearity clause of well-formedness preservation is machine-checked end to end, and the laws themselves are machine-checked in pushout-normal form (the aligned-stratum gluing of section 10.6: well-formedness closure, the relational composition law with the determinism hypothesis deleted, unit and associativity on the nose). The bridge — that the port-map, seam-repair, and renumbering construction of this chapter reduces to that normal form — is machine-checked in the same tree (Qtsl.SubstitutionBridge): under the port-validity hypotheses and the no-taps interface discipline, the raw composite is field-for-field the aligned gluing of the padded inner hypernet, the seam-repair block taken verbatim as the structural interpolant, and the redirected outer hypernet (substituteRaw\_eq\_glue), so substitution is the canonical renumbering of an aligned-stratum glue (substitute\_eq\_glue\_renumber) — the structural reshuffle of the prose statement absorbed into the choice of interface lists — and the relational composition law applies to the substitution itself (substituteOpen\_admissible\_iff); sorry-free, axiom census the standard classical base. The presentation of this chapter and the normal form it reduces to are thereby machine-checked as one construction.

**Design tense.** Higher-order hypernets (function-space wires — wanted by no modelling frame currently in scope, and deliberately unbuilt until one forces them); the block-ordering convention that would sharpen the commutation of substitutions into *disjoint* port sets from convention-conditional to unconditional; and the plate producer surface (the wire-format extent tag with its backward-compatibility golden, builder support, and the packaged count symbol — the pieces named in section 10.4’s status paragraph). All have written design records; nothing stated above depends on any of them.

# Hypernets: Markov Kernels

DRAFT

Chapter 10 fixed a deterministic calculus: ten primitive boxes, one evaluator, one canonical serialization, one content digest. Stochastic models need kernels: a diffusion with jumps needs a jump law, a stochastic Petri-style transition needs a firing law, and a Markov chain simply *is* its transition kernel. This chapter is about how the toolkit says “Markov kernel” without adding a primitive. A *Markov-kernel hypernet* is an ordinary well-formed hypernet together with a designated roster of *noise ports*: inputs read as fresh uniform draws on  $[0, 1]$ . Its denotation is the Markov kernel obtained by pushing the uniform reference measure forward through the deterministic semantics — every kernel is presented by an explicit deterministic dilation with its ancilla exposed. Randomness enters at the interface, never at a box; the wire format, the evaluator, and the digest scheme never learn that the extension exists. A reader who only wants to know which named distributions the toolkit provides can go straight to the coverage dashboard (section 11.4).

## 11.1 Kernels as dilations

Three consequences of this reading come essentially for free. *Normalization is a theorem, not a constraint*: every box is total and the reference measure is a probability, so nothing expressible at this level loses mass. *Discard is marginalization*: deleting an output wire marginalizes the kernel. *Copy is sharing, never resampling*: fan-out of a noise-derived value is an explicit copy row — both consumers see one realization — while an independent resample is a second noise port, so the two are different graphs with different digests. The last point is a central subtlety of the probabilistic string-diagram literature (tossing a coin and copying the outcome is not tossing two coins [25, 84]), and the linearity discipline of the deterministic calculus settles it structurally, with no new axioms; Figure 11.1 draws the two graphs.

All three consequences are machine-checked in the toolkit’s Lean tree at the finite-outcome stratum, where a stage is a measurable outcome map from the noise cube  $[0, 1]^N$  to a finite value set. Total mass one is the theorem `sum_noiseDenotFun`; pushing the denotation forward along a projection is `noiseDenot_comp`, with `discard` as the special case that forgets a coordinate. For composition, the law runs in the positive direction and in the negative one: with disjoint noise rosters, a sequential composite denotes the Kleisli composite of the stage denotations (`noiseDenot_seqComp`), while a shared roster provably departs from that composite (`copy_ne_kleisli`), so the disjointness hypothesis is content rather than bookkeeping. All of these live in the namespace `SuFunctor.Stochastic`, sorry-free.

The evaluator never samples: given noise values as ordinary rational inputs, the exact evaluator runs unchanged. Simulation is the evaluator plus an external random-number driver; certificates consume the kernel’s polynomial data and the reference measure, never samples.

## 11.2 Jump structure: mass, intensity, thinning

Continuous time asks for more than normalized kernels. Jump structure contributes a jump measure and a killing rate to a process’s extended generator [60, 69], and what must be tracked is *mass*: rates scale it, killing removes it, and staying put carries it without moving. The kernel vocabulary for this tier is a small generator language over normalized kernels — jump, stay, kill, scale, superposition, and the empty generator — in which every term carries a rational *intensity majorant*, computed by the typing derivation: scale multiplies it, superposition adds it. State-dependent intensities  $\lambda(x)$  recover from a scalar majorant  $\Lambda$  by thinning: run the clock at rate  $\Lambda$  and, at each ring, branch to the real jump with probability  $\lambda(x)/\Lambda$ , staying put otherwise.

Figure 11.1: Copy is sharing, never resampling. Fanning a noise port out through an explicit copy (left) hands both consumers one realization; an independent redraw is a second noise port (right). The two are different graphs with different digests, and their denotations provably differ (`copy_ne_kleisli`).

Killing is deliberately distinct from the mass-preserving discard, and stay is deliberately distinct from zero: a stay contributes nothing to the generator but carries mass in the grading, which is what thinning and simulation budgets need to see.

This vocabulary is machine-checked too — at the finite-state stratum, in the same sorry-free module family as the dilation theorems. Every term elaborates, by structural induction, to a *thinning normal form* (`ThinningForm`): a majorant together with one normalized kernel into the state space extended by two tagged outcomes, stay and kill. A sub-stochastic mass deficit is therefore unrepresentable rather than merely discouraged. The elaboration cannot emit sub-mass, and the declared intensity distributes exactly over the named channels (`elaborate_mass_partition`, with `outflow_le_intensity` giving the majorant its meaning). Elaboration itself preserves the extended generator (`generator_elaborate`). The normal form is deliberately non-unique, and its two semantics-preserving moves are themselves theorems: a majorant may be inflated with the slack paid to stay (`generator_dilate`), and self-jump mass may be reclassified as stay (`generator_absorbDiagonal`) — killing mass may not, which is the kill/stay separation made mechanical. Composition is machine-checked at the same stratum (module `SuFunctor.Stochastic.JumpAlgebra`): the normal forms carry the term vocabulary’s composite algebra — superposition, thinning-scale, coordinate extension, and parallel interleaving, with the intensity majorants as its grading — and elaboration is a homomorphism of that graded algebra, definitionally for the module operations (`elaborate_superpose` and its kin close by `rfl`) and in the thinning quotient for interleaving (`generator_elaborate_interleave`); sequential composition of jump kernels is no part of this tier’s algebra by design — successive jumps compose through time, and the Kleisli law for discrete steps is section 11.1’s. The same tagged form recovers the jump-diffusion generator of chapter 12. That chapter’s legacy encoding reads a reset mixture’s mass deficit as killing, in Davis’s convention; rewriting each deficit into an explicit kill outcome leaves the legacy transfer increment unchanged, and the full generator is recovered with nothing sub-stochastic remaining (`generator_eq_stepMix`). Every well-typed term thus declares a finite intensity majorant, the same bounded-intensity condition the non-Zeno arguments elsewhere in this book compose with.

One consumer is worth naming here: the supervisors of the composition inventory (section 13.11) are ordinary jump-only Systems — policy memory is marking, and a policy update’s stochastic content is a firing kernel of this tier — so control through enablement adds no kernel vocabulary of its own.

### 11.3 Packaged generators

Two families of packaged generators round out the vocabulary, both in the packaged-symbol discipline of chapter 10 (a definitional expansion, a projection lemma, and a candidacy rule — never a new box).<sup>1</sup> *Distribution generators* name the classical laws: each is an alias for a certified piecewise-polynomial quantile table applied to a noise port, carrying an explicit accuracy budget, so that a model that draws from a named distribution elaborates into the same hypernet language every other certificate in this book speaks. Section 11.4 is their coverage dashboard. The *stochastic-matrix generator* covers the finite-state case directly: a kernel between finite-extent wires given by an explicit tensor of transition probabilities, whose key conformance obligation is row-stochasticity — mass one from each source state — making finite Markov chains and the jump chains of continuous-time models first-class citizens rather than encodings.

<sup>1</sup>Two senses of *generator* meet in this chapter: the analyst’s (section 11.2 presents extended generators) and the algebraist’s (a packaged generator is a named symbol with a definitional expansion). The word is inherited from both literatures; the toolkit keeps the senses apart by type.

A status note, in the spirit of the preview note at the front of this volume. The deterministic substrate is chapter 10's and is shipped. The denotational core of the noise-port reading — normalization, discard as marginalization, the Kleisli composition law and its shared-roster failure — is machine-checked at the finite-outcome stratum (section 11.1), and the jump vocabulary's semantics — the intensity grading, the thinning normal form, its soundness, and the thinning-quotient moves — are machine-checked at the finite-state stratum (section 11.2). The kernel-language *surface* has meanwhile settled: the certificate theory (theories/Qtsl.geolog) carries it as normative schema. A kernel citation there names its hypernet by digest together with its noise roster and three tagged outcome channels: *next*, *stay*, and *cemetery*, the wire format's name for the kill outcome. With every unit of mass explicitly named by one of the three channels, a sub-stochastic deficit is unrepresentable, and a pure kill is a weight-one cemetery branch.

A transition carries a *clock* with three wings, and the wing decides when the kernel is consulted. A *racing* clock declares its intensity majorant. At a finite majorant, its polynomial presentation elaborates definitionally into the thinning normal form of section 11.2; the infinite majorant instead marks the instant-fire boundary case, contributing no generator term. A *demonic* clock has no timing law — whether and when its kernel is consulted belongs to a scheduler over which every judgment quantifies — but carries a strictly positive dwell floor in the system definition: the scheduler may fire the transition only after that much contiguous dwell inside its guard region. A row with floor  $d$  therefore fires at most  $T/d + 1$  times by horizon  $T$  under every resolution, and the demonic wing cannot produce Zeno behaviour at all. An untimed Petri net transcribes with unit dwell floors: the transcription is its *discrete-time unfolding*, embedded in the continuous-time frame. It is faithful for ordering-and-counting properties, which are all an untimed net ever asserted. A *forced* clock fires at exactly its declared positive dwell of contiguous in-guard time: deterministic delay, completing the triple — exponential, immediate, deterministic — from which deterministic and stochastic Petri nets are built, so watchdogs, timeouts, and protocol timers are native rows rather than encodings. Preemption is by guard reset (whatever fires first wins, and the forced clock resets with its guard). A same-instant tie between two forced transitions resolves through the demonic scheduler's seat: the classical deterministic-net literature needs an ad-hoc tie-breaking convention exactly where an imprecise-probability semantics has a seat already waiting. With both dwell floors strictly positive, the one syntactically visible source of Zeno behaviour in the vocabulary is an unbounded chain of instant firings — precisely what the crossing-budget certificates price.

The stochastic-matrix generator is carried with row-stochasticity among its named conformance obligations. The certified quantile tables behind the dashboard's certified rows exist today as test-suite artefacts, and the dashboard section states, row by row, what each status rests on and what would move it. This chapter still owes the settled surface its presentation: a coming revision states it at the deterministic calculus's level of rigour, with its soundness against the semantic universe, and a section on firing kernels alongside.

## 11.4 Distribution generators: a coverage dashboard

The toolkit's stochastic vocabulary needs named random variates the way its deterministic vocabulary needs elementary functions, and it admits them under the same discipline: never as new primitives. A *distribution generator* is a packaged symbol whose expansion is a certified piecewise-polynomial quantile table applied to uniform noise ports, so a model that draws from a named distribution elaborates — before anything is checked — into the same hypernet language every other certificate in this book speaks (chapter 10). Checkers and certificate formats learn nothing new; being wrong in a table costs a rejected certificate, never a false verdict.

Each generator registers with an explicit budget  $(\varepsilon; \delta_{lo}, \delta_{hi})$ : quantile sup-error at most  $\varepsilon$  on the core  $[\delta_{lo}, 1 - \delta_{hi}]$ , in the family's standard scale, with the clipped tail mass declared per side. The working target is  $\varepsilon \leq 2^{-23}$  — single-precision machine epsilon — with default clips of  $2^{-30}$ ; heavy-tailed families declare conspicuously larger honest clips rather than pretending to a tail no polynomial reaches, and multiplicative families state  $\varepsilon$  relatively. Verification never encloses an inverse transcendental: each certificate drives the *forward* CDF through polynomial enclosures, piece by piece in a rescaled frame, and closes with a residual row, a derivative-floor row, and one rational comparison. A verification class grades what forward material that takes: **V0** nothing (the construction is exact), **V1** polynomials only, **V2** the mechanized elementary enclosures (exponential, sine, cosine, the error function, and now the incomplete gamma), **V2q** certified quadrature, **V3** an enclosure family built specially for the row that needs it (to date one exists: the incomplete beta, whose tail lemma is its own). Every certified row also ships a refusal battery in the sense

the Experiments chapter (chapter 2) makes precise: tampered coefficients, shaved residuals, dishonest tail declarations, partition gaps, and dropped budget-composition terms must each be refused by a named row.

**Enclosures are certified valid unconditionally.** The core range bounds where the *tightness* claim lives, not where validity ends: a generator’s certificate is a bundle of unconditional theorems, and no row’s truth is scoped to the core. The enclosures are also certified to be *tight* to single-precision machine epsilon within their core range (the working target; a row that declares a different  $\varepsilon$  says so in the dashboard), and outside the core they degrade honestly, in two genre-specific ways, because the two kinds of table stand on different input axes. A quantile table’s axis carries the probability measure itself, so the table is total on  $[0, 1]$ : its end cells clamp to exact rational constants, and the clamp-honesty rows certify that the mass beyond each clamp is at most the declared  $\delta$  — a checked row, never trust. Monotonicity keeps even the off-core bracket better than trivial: beyond the core the true quantile stays pinned between the certified core-edge value and the support boundary, a certified inference wherever the monotonicity rows are claimed, so the generated law couples to the named law within  $\varepsilon$  except on an event of probability at most  $\delta_{lo} + \delta_{hi}$ . A function table — a certified polynomial approximant of a plain function on a declared domain, the wrappers among them — stands on an axis that carries no measure, so there is no tail mass with which to pay for a clamp: off its declared domain such a table simply makes no claim, and an off-domain evaluation degrades to the trivial bracket — nothing is known about this number — which is still a valid statement, never an assertion of impossibility. Refusal, where it appears in this discipline, is a judgment about claims rather than about numbers, and it lives at production and certification time: a producer declines to emit a table it cannot cover, and a checker refuses a tightness claim over domain a table does not cover. The dashboard’s  $\times$  against the unbounded uniform is different in kind from all of this: there the family itself admits no quantile function, an impossibility of the mathematics rather than a limit of a table’s coverage.

**The census.** Coverage is measured against an external standard the toolkit does not own: Crooks’ *Field Guide to Continuous Probability Distributions* [51], whose numbering organizes some 170 named forms into on the order of a hundred sections related by an explicit lattice of limits, reparametrizations, and transforms. The Field Guide’s own section numbers are the census: every numbered form appears in exactly one row below (block rows name the sections they cover; synonyms resolve to the section they cite — Lorentzian to Cauchy, Fisk to log-logistic, fatigue-life to Birnbaum–Saunders). The *route* column says how the family is reached — *exact* (arrow algebra over existing generators: order statistics, sums, products, mixtures, folds), *composition* (certified wrappers over the two quantile roots), *own table* (a directly-tabled quantile where that is cheaper than composition), or *dispatch* (a parameter-time classification to a member family) — with the verification class in parentheses. The *status* column is the dashboard: *certified* rows carry receipts as described above; *routed* rows have a fixed construction and verification class but no table yet; *out of scope* rows are deliberate, each with the honest reason, the priced alternative, and the condition that would reopen it. Two roots (the standard exponential and standard normal quantiles) and three wrappers (rational powers, logarithm, exponential) generate everything except the own-table rows; location-scale families register one standard table each, extended by exact affine arrows.

Each row carries a mark in the same vocabulary as the QTSL rule catalogue’s coverage dashboard:  $\checkmark$  certified,  $\sim$  routed (construction and verification class fixed, no table yet),  $\times$  out of scope;  $\checkmark \sim$  marks a row certified for its named part with the residue routed.

**Shared infrastructure (roots, wrappers, constants).**

| object                                                                                                                | status |                                                     |
|-----------------------------------------------------------------------------------------------------------------------|--------|-----------------------------------------------------|
| exponential quantile root (the registered standard exponential)                                                       | ✓      | certified — $\varepsilon \leq 4.3 \times 10^{-8}$   |
| error-function forward enclosure (mechanized; soundness stated against the Gaussian integral, standard axioms only)   | ✓      | certified                                           |
| probit quantile root (the registered standard normal)                                                                 | ✓      | certified — $\varepsilon \leq 2.9 \times 10^{-8}$   |
| rational-power wrapper (reciprocal and square root included)                                                          | ✓      | certified — per-instance $\varepsilon \leq 2^{-24}$ |
| logarithm wrapper (verified through the exponential's forward enclosure — no logarithm enclosure exists or is needed) | ✓      | certified — $\varepsilon \leq 2 \times 10^{-9}$     |
| exponential wrapper (sinh, cosh derived exactly)                                                                      | ✓      | certified — relative-error native                   |
| certified constants ( $\ln 2$ , $\pi$ , $2/\sqrt{\pi}$ )                                                              | ✓      | certified — relative half-width $\leq 2^{-55}$      |
| composition algebra: exact budget arithmetic per arrow, with a route audit that refuses any dropped term              | ✓      | certified                                           |

**Zero shape parameters (Field Guide ch. 1–4).**

| §   | family                                        | route            | status |                                                                                                                         |
|-----|-----------------------------------------------|------------------|--------|-------------------------------------------------------------------------------------------------------------------------|
| 1.1 | uniform (half uniform; degenerate point mass) | exact (V0)       | ✓      | certified — exact                                                                                                       |
| 1.— | unbounded uniform                             | —                | ✗      | out of scope — improper (not normalizable), so no quantile function exists; set-valued premises cover the intended uses |
| 2.1 | exponential (anchored, standard)              | composition (V2) | ✓      | certified — $\varepsilon \leq 2^{-24}$                                                                                  |
| 3.1 | Laplace                                       | composition (V2) | ✓      | certified — $\varepsilon \leq 2^{-24}$                                                                                  |
| 4.1 | normal                                        | composition (V2) | ✓      | certified — $\varepsilon \leq 2.9 \times 10^{-8}$ at unit scale (exact affine scaling)                                  |

## One shape parameter (ch. 5–9).

| §    | family                                                                           | route            |   | status                                                                                                                                                |
|------|----------------------------------------------------------------------------------|------------------|---|-------------------------------------------------------------------------------------------------------------------------------------------------------|
| 5.1  | power function (generalized Pareto, $q$ -exponential reparametrizations)         | composition (V1) | ✓ | certified — $\varepsilon \leq 2^{-23}$                                                                                                                |
| 5.4  | wedge (ascending, descending)                                                    | exact (V0)       | ✓ | certified — exact                                                                                                                                     |
| 5.5  | Pareto (Lomax 5.6 = shifted)                                                     | composition (V1) | ✓ | certified — $\varepsilon \leq 2^{-23}$ (moderate core; the wide core is deep-tail-dominated and its excluded mass is declared)                        |
| 5.7  | exponential ratio (uniform-prime 5.8; Lomax(1))                                  | composition (V1) | ✓ | certified — $\varepsilon \leq 2^{-23}$                                                                                                                |
| 6.1  | log-normal (Gibrat)                                                              | composition (V2) | ✓ | certified — relative $\varepsilon \leq 2^{-23}$                                                                                                       |
| 7.1a | gamma, integer shape (Erlang)                                                    | exact (V2)       | ✓ | certified — $\varepsilon \leq 2^{-24}$ (three-port pin; per-port tables pre-tightened so sums stay under target)                                      |
| 7.1b | gamma, half-integer shape                                                        | exact (V2)       | ✓ | certified — declared per alias — the squared-clamp amplification is stated at its measured value (e.g. $3.5 \times 10^{-7}$ at one degree of freedom) |
| 7.1c | gamma, general rational shape                                                    | enclosure (V2)   | ✓ | certified — $\varepsilon \leq 2^{-23}$ at the pinned fractional shapes (measured $2^{-27}$ -class)                                                    |
| 7.3  | chi-square (scaled; Porter–Thomas)                                               | exact (V2)       | ✓ | certified — $\varepsilon \leq 2^{-24}$ at even $k$ ; odd $k$ declared per alias                                                                       |
| 8.1  | gamma-exponential<br>(chi-square-exponential;<br>generalized Gumbel)             | composition (V2) | ✓ | certified — $\varepsilon \leq 2^{-23}$ (integer shapes); half-integer members inherit the squared-clamp declaration                                   |
| 8.5  | Gumbel                                                                           | composition (V2) | ✓ | certified — $\varepsilon \leq 2^{-26}$                                                                                                                |
| 8.7  | BHP                                                                              | composition (V2) | ✓ | certified — $\varepsilon \leq 2^{-23}$ at the irrational shape $\pi/2$ (a bracketed-shape pin plus an exact shape-transfer argument)                  |
| 8.8  | Moyal                                                                            | composition (V2) | ✓ | certified — $\varepsilon \leq 2^{-23}$                                                                                                                |
| 9.1  | Pearson VII, half-integer $m$<br>(Student $t$ , integer $\nu$ ;<br>Breit–Wigner) | composition (V2) | ✓ | certified — declared per floor — the heavy tail's excluded-event mass is priced exactly, and the sup concentrates in near-floor tail events           |
| 9.4  | Student $t_3$ (the odd- $\nu$ pattern)                                           | own table (V2)   | ✓ | certified — $\varepsilon \leq 2^{-26}$                                                                                                                |
| 9.6  | Cauchy (Lorentzian; $t_1$ )                                                      | own table (V2)   | ✓ | certified — $\varepsilon \leq 2^{-23}$                                                                                                                |

**Two shape parameters (ch. 10–12).**

| §     | family                                                                                                                                                        | route               |   | status                                                                                                                                                                                                                                       |
|-------|---------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------|---|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 10.1  | unit gamma                                                                                                                                                    | composition (V2)    | ✓ | certified — $\varepsilon \leq 2^{-23}$ (relative $\leq 2^{-38}$ at the standard pins); half-integer members declare their relative error                                                                                                     |
| 10.2  | uniform product                                                                                                                                               | exact (V0)          | ✓ | certified — exact                                                                                                                                                                                                                            |
| 11.1  | Amoroso (Stacy = anchored)                                                                                                                                    | composition (V1+V2) | ✓ | certified — $\varepsilon \leq 2^{-23}$ (integer and half-integer pins; both signs of the power parameter — the inverse-Amoroso branch included)                                                                                              |
| 11.7  | half-normal                                                                                                                                                   | exact (V2)          | ✓ | certified — $\varepsilon \leq 2.9 \times 10^{-8}$ at unit scale; no clipped mass at the support edge                                                                                                                                         |
| 11.8  | chi (Rayleigh, Maxwell, Nakagami)                                                                                                                             | composition (V2)    | ✓ | certified — $\varepsilon \leq 2^{-23}$                                                                                                                                                                                                       |

**What the statuses rest on.** Status column as of July 27, 2026; it will move with each preview. Unlike the tables of the Experiments chapter, this section’s rows are not yet re-derived by the experiments repository’s make targets: the dashboard re-derives from the toolkit workshop’s census of record, and the certificates behind the certified rows live at this date in the toolkit repository as ordinary test-suite artefacts (accept fixtures at the declared budgets plus their refusal batteries). Migrating them onto the experiments repository’s reproduction spine — regenerated as the same sealed containers that chapter’s fluid-drift certificates already ride, re-verified by the blessed checkers, one make target for the family — is named successor work, and this section’s tables will then re-derive from committed receipts like every table of the Experiments chapter. Per the preview note at the front of this volume, until an artefact appears in the public repositories, treat its mention as a statement of what exists, not yet a link.

# Systems: Mathematical Models

DRAFT

Chapter 9 lays out the universe these profiles present into, with its records, its structured time base, its imprecise denotation, and its composition calculus. The statuses below grade each frame against that semantics. The grading has a stated division of labour: most entries give the frame’s own rung in their *Semantics* paragraph — a generator, a path measure, a solution concept — and the bridge lemmas, staged as named obligations and discharged frame by frame, then make up the distance between that rung and the record-space denotation. Where an entry’s semantic content *is* an interpretation into the universe’s objects, as with the Bag former’s carrier colimits or the credal reading of quantification over policies, the entry carries the interpretation explicitly.

Throughout this book a *System* means a structured presentation, a composition term over *mechanisms* and *wirings*. A mechanism is a primitive dynamics declaration: a family of fields over declared state variables together with an interface binding. A wiring identifies variables across interfaces, subject to causality and simultaneity side conditions. A System is never the semantic quotient of the dynamics it presents, and in particular it is never the infinitesimal generator. The generator re-enters one level down, as the certification interface, which compiles mechanism rows into the obligation rows the exact kernel checks. Time is base-universal. Composites live on real time, clocks are internalized as mechanism state, and a discrete-time component taken in isolation is schedule-generic, acquiring its schedule assumptions exactly at the boundary where it composes with continuous neighbours.

One consequence organizes this chapter: **a model type is a profile, not a tag**. Nothing in the theory stores “this model is a stochastic differential equation”. A model’s type consists in *which field families its mechanisms populate*, and a composite may mix profiles freely. Ordinary engineering forces this design. Hybrid stochastic systems must be first-class citizens, and a robot — any robot — is a mixed discrete/continuous composite that must type-check across its own components. A stored per-model doctrine tag fails both requirements, whereas a profile satisfies both by construction. The sections below give the normative inventory of those profiles, at the granularity a modeller shops at. A companion human-facing book, *Mathematical Modelling with MAITRIA*, will treat modelling as a discipline in its own right, while this chapter takes only what a toolkit user needs.

The roster of sections is not ours. It is the list of modelling frames that the Safeguarded AI programme thesis (David “davidad” Dalrymple, *Safeguarded AI: Constructing Guaranteed Safety*, ARIA) [55] sets out in its Appendix A.1 as the frames a unified modelling language should subsume — the same TA1.1/TA1.2 rubric the rest of this book grades itself against. Grading a candidate language against that list is itself programme-native. In a December 2023 programme talk, davidad ran the exercise, scoring the identical list against stochastically and dynamically coloured Petri nets (SDCPN, section 12.18) as the candidate unifier. Two cells came back not-covered in 2023, deterministic and stochastic partial differential equations, and the deterministic half is where the present stack has landed some of its freshest certificates (section 12.5). We read that as evidence that the candidate graded here is not merely re-walking SDCPN’s coverage, and we keep the grading honest for the same reason the 2023 slide did, since the value of the exercise lies in the map of what remains.

The catalogue itself runs wider than the 2023 list. This chapter presents the *Model Types* wing of a two-winged *System Catalogue*, with model types here and composition patterns in chapter 13. The catalogue’s roster also carries the substrate every profile populates (the System core, section 12.1; tick declarations, section 12.2) together with the types in production use beyond the list (clocked circuits, the Bag former, SDCPN, the i.i.d. tier), and one frame beyond the list whose mechanized semantics arrived ahead of any producer surface: the quantum nets of section 12.25. Every entry, on the list or beyond it, follows the same section grammar.

**How to read the sections.** Every section carries the same four rubrics, adapted from the working catalogue's entry format. *The frame* says what the model class is, and gives its bread-and-butter verification question. *Profile* says which field families a model of this type populates: content language, carrier, disturbance semantics, and time semantics. *Semantics* names the bridge-obligation class its satisfaction claims discharge, and every analytic lemma that licenses reading exact algebra as a statement about trajectories or measures is *staged as a named hypothesis*, never silently assumed. *Status* gives the state of four legs, each graded only against a witness (below). Each entry then closes with two blocks in the Rule Catalogue's grammar. The first, a *Computer Science Metanotation* block, gives the entry's *term former*, an inference rule whose premises are the formation data the builders consume, with their sorts, and whose conclusion is a primitive judgment at the sort System (or at the entry's own true sort, where an entry declares vocabulary rather than forming a System). The second, an *API* block, gives the producer surfaces (TypeScript, then Rust) with signatures and constructions extracted from the toolkit sources at every regeneration of this catalogue. Frontier entries (section 12.26) carry neither, since no producer surface exists for them at this preview, and an invented one would defeat the grading. The wiring-pattern entries (delay differential equations, section 12.6; partially observable decision processes, section 12.14) also carry neither, deliberately: each of those frames *is* a composite of other formers, and the absence of a former of its own is the entry's content. The quantum entry (section 12.25) sits between the two conventions: its formation rule stands on mechanized Lean ground truth, so it appears; its API block waits for a producer surface to exist. The four legs —

- **representation:** a model of the frame is declarable as rows of the modelling language in a form a frame-native reader recognizes as *their* model, with the frame's compositional grain preserved rather than flattened by an encoding trick;
- **semantics:** the frame's standard semantics is recovered, either exactly or at a named rung with the bridging hypotheses staged;
- **certification:** at least one of the frame's own bread-and-butter questions compiles to obligations checked by the *unmodified* exact kernel, with a shipped exact-rational artefact;
- **compositional closure:** the frame's systems compose with systems of *other* frames through the patterns of chapter 13, with certificates transported across the composite boundary and witnessed by shipped artefacts rather than design prose. A frame can pass the first three legs and still be flattened at its composition boundaries, and this leg exists to detect exactly that. Where a frame's semantics genuinely cannot instantiate a pattern's composition data (a static distribution has no internal time axis for a supervisory switch to sequence), the omission is earned by a filed argument from the frame's own semantics, never by a bare declaration.

As of this preview, *no frame on the list passes all four legs*, and exactly one (ordinary differential equations) holds a cross-frame composition witness. The statuses below serve as the campaign's map rather than a victory lap. They are re-graded at each preview, and several moved in the week this chapter was drafted. We publish the grades at this granularity because the alternative, a coverage matrix of green ticks, is how unification claims usually go wrong.

**How to read this chapter.** The sections run in parallel, with the same rubrics in the same order, so a reader may take them in any order and sample by interest. A reader new to the catalogue should read two entries in full. Ordinary differential equations (section 12.4) carry the catalogue's simplest square, and discrete-time Markov chains (section 12.11) carry the square that is the engine most later squares reuse. After those two, every other entry is a variation on a theme the reader already knows, each adding one idea. Four entries repay attention even from a reader in a hurry: the delay line (section 12.6), which dissolves an apparently new semantic species into a wiring pattern over inventory the catalogue already has; the demonic faces of sections 12.13 and 12.15, where the adequacy squares first become set-valued; the coloured nets of section 12.18, where the 2023 candidate unifier is itself compiled into the catalogue it was once graded against; and the quantum nets of section 12.25, the one entry whose set-valued face is demanded by a theorem of its own literature rather than chosen by the modeller. The formal blocks closing each entry serve as reference material, so skip them on a first pass, and return to them when declaring a model.

Figure 12.1: The adequacy square that this chapter’s Adequacy paragraphs instantiate. At the two-sided entries the two routes agree by an invertible globular cell; at the martingale–problem entries (stochastic and jump–diffusion) the cell runs one way, from the community’s semantics to the certified verdict. The middle column of the table below grades this square, frame by frame.

**The list at a glance.** The middle column grades each entry’s *adequacy square* (Figure 12.1), the mechanized statement, carried in the entry’s Adequacy paragraphs, that compiling a model and then denoting it agrees with interpreting it classically and then including the classical object. The outer columns grade certification, and dashes mean nothing shipped.

| frame                | adequacy square                                                                                                                                                         | certified today                                                                                                  | principal gap                                      |

A single content language carries the whole continuous and hybrid family below, a manifest vocabulary of modes with domains, drift, diffusion, multi-driver noise, jumps, and guarded transitions with resets, and the types differ only in which fields are populated. Content-addressed references carry neural and piecewise content (a network controller in the loop, a learned drift) on any of these profiles, and where a polynomial view coexists with network content, their agreement is a recomputation obligation, never a trusted row. Discrete-kernel types present outcome rows, while nets and graphical models carry their own small theories, described in place.

## 12.1 The System Core

**The entry.** The substrate every profile populates: the manifest root, its two strata, and the family view that makes “profile, not tag” an operational sentence rather than a slogan. A System manifest is a composition term — a *mechanism* (the primitive-dynamics stratum: field families over declared state variables plus an interface binding) or a *composite* (the wiring stratum: component Systems plus variable-identification rows and the composite-level descriptors of chapter 13) — the mechanisms-and-wirings reading of systems whose doctrinal home is the double operadic theory of Libkind and Myers [163]. Every field family of a mechanism is individually optional at the type level; the free-form entry point never refuses, because any family combination is a legal *presentation* — conformance to a named profile is a separate, optional check (the presets of the sections below), and a mechanism whose populated set matches no preset is a first-class citizen. That check, in plain words and stated here once for the whole chapter: a manifest *conforms* to a model type when it populates that type’s field families and no others beyond the shared substrate ( $\Sigma$ , below); the preset signatures quoted in each entry’s API block are the mechanized form of exactly that check. No time-semantics tag is stored anywhere: continuous, counter, or hybrid is derivable from which families are populated, and storing it would be exactly the per-model doctrine tag this catalogue rules out.

**Trust posture.** Presets and the preflight walk are courtesies — profile notes and dangling-reference warnings with path geometry, never verdicts; the checker’s replay is the only authority on content. On the wire the manifest is CBOR under a schema-versioned envelope with exact scalars; the committed golden vectors are the cross-language byte authorities, and the TypeScript surface reaches the same Rust implementation in-process, so the two surfaces cannot diverge.

### Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\begin{array}{c}
 \vec{x} : \overrightarrow{\text{StateVar}} \quad \Sigma_m \text{ substrate rows over } \vec{x} \text{ } (\Sigma, \text{ below}) \\
 \Phi \subseteq \mathcal{F} \quad F_\phi : \overrightarrow{\text{Row}}_\phi \quad (\phi \in \Phi) \\
 \hline
 \text{Mechanism}(\vec{x}; \Sigma_m; (F_\phi)_{\phi \in \Phi}) : \text{System} \quad \text{MECHANISM}
 \end{array}$$
  

$$\begin{array}{c}
 S_1, \dots, S_k : \text{System} \quad W : \overrightarrow{\text{WiringRow}} \quad E : \overrightarrow{\text{SwitchEdge}} \quad A : \overrightarrow{\text{ScheduleAssumption}} \\
 \hline
 \text{Composite}(S_1, \dots, S_k; W; E; A) : \text{System} \quad \text{COMPOSITE}
 \end{array}$$

The two primitive System formers. The family alphabet  $\mathcal{F}$  mirrors, group for group, the field families of the manifest schema (the `MechanismInit` groups of the API block below):

|                                                                                                                  |                         |
|------------------------------------------------------------------------------------------------------------------|-------------------------|
| $\mathcal{F} = \{\text{modes, drift, lagrangian, diffusion, noise, noise\_spectrum, jumps, kill, transitions}\}$ | continuous / hybrid     |
| $\cup \{\text{outcomes, init\_dist, rates, scheduler, circuit}\}$                                                | discrete-kernel         |
| $\cup \{\text{tick}\}$                                                                                           | counter time            |
| $\cup \{\text{petri, bag, sdcpn, stochastic\_wires, equations, interventions, exogenous, weighted\_program}\}$   | relational / population |

Each family’s row sort  $\text{Row}_\phi$  is the family’s own, given by the formation rule of the entry that consumes it. Every entry below is a checked specialization of Mechanism: its head form carries the formation data that individuates its type, and optional declarations (marked ?) are consumed without appearing in it. No premise constrains  $\Phi$  — any family set is well-formed formation data, and a mechanism whose populated set matches no preset is a first-class citizen. That the toolkit’s free entry point never refuses is the implementation face of this rule: a forward-compatibility property (families added to  $\mathcal{F}$  extend the schema without invalidating old manifests), not a logical feature. On the wire, either former’s term is carried in

the manifest record  $\langle \text{schema}, v, \text{name?}, \text{term} \rangle$ .  $\text{pop}(m) = \Phi$  is a view, recomputed on demand and never stored. The substrate families, admitted alongside every former's own formation data without being listed:

$$\Sigma = \{\text{state}, \text{params}, \text{interface}, \text{init}, \text{hypernet\_refs}, \text{pinning}\}.$$

## API

Producer surface of the mtk toolkit for this entry: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named  $\text{fx\_}$  or  $\text{f.}$  are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.buildSystem`

signature — `ts/src/system.ts`

```
export function buildSystem(init: MechanismInit & SystemOpts): System

  // i.i.d. tier
  readonly pinning?: PinningDecl;
}
```

construction — `ts/tests/system-native.test.ts`

```

const init = {
  name: "ou-ld",
  state: [{ id: 0, name: "x" }],
  drift: [{ var: 0, poly: mono(1, 0, 1, "-1") }],
  diffusion: [{ var: 0, poly: constant(1, "1/2") }],
  init: { kind: "point", coords: [BIG] },
} as const;
const viaPreset = sys.unwrap(sys.sde(init));
const viaFree = sys.buildSystem(init);
assert.ok(viaPreset.contentEquals(viaFree));
assert.equal(toHex(viaPreset.toCbor()), toHex(viaFree.toCbor()));

```

The quoted corpus lines run the corpus's preset discipline as an assertion: a preset's output is byte-identical to buildSystem's on the same mechanism — presets add checking, never representation.

### Rust mtk\_catalogue::system::SystemManifest

signature — crates/mtk-catalogue/src/system/manifest.rs

```

pub fn free(mechanism: Mechanism) -> Self
pub fn composite(composite: Composite) -> Self

```

construction — crates/mtk-catalogue/tests/builders.rs

```

assert_eq!(known_profile(&drift_only(), Some("ODE")));
let free = SystemManifest::free(drift_only());
// Nothing on the wire stores the classification: same bytes with
// or without the preset having been consulted.
let via_preset = Ode::manifest(drift_only()).unwrap();
assert_eq!(free.to_cbor().unwrap(), via_preset.to_cbor().unwrap());

```

The quoted corpus lines assert the profile-not-tag doctrine on the wire: same bytes with or without the preset having been consulted.

## 12.2 Tick Declarations

**The entry.** The composition-critical counter-time vocabulary. Time is base-universal — composites live on real time — so a counter-time mechanism composed into real time declares its tick as a timer mechanism whose reset parameter is either a point (*exact tick*) or a box (*jitter bracket*). The distinction is part of the model type, not a checker convention, and it has been priced by certificate: a lander free-flight pair certifies the same funnel under both semantics from one value table and one cover, with the cost of clock jitter a factor of 2.66 in certified ticks-to-funnel (1631 against 614), and a factor 2.92 in the certified elapsed bound, since a jittered tick may run a tenth longer than an exact one. Both horizons are upper bounds carried by the certificate, not measured times. A discrete-time component in isolation remains schedule-generic; its schedule class becomes *assumption data* exactly at the discrete/continuous composition boundary, through the hybrid-time pattern of chapter 13.

### Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (crates/mtk-catalogue/src/system/), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{\text{period} \in \mathbb{Q}_{>0}}{\text{exact}(\text{period}) : \text{TickDecl}} \text{EXACT} \qquad \frac{\text{lo}, \text{hi} \in \mathbb{Q}}{\text{jitter}([\text{lo}, \text{hi}]) : \text{TickDecl}} \text{JITTER}$$

Not a System former: the conclusion is at the declaration's own sort. A TickDecl is carried either on the mechanism itself (tick  $\in \text{pop}(m)$ , admitted by the counter-time profiles) or in a composite's assumption slot as ScheduleAssumption = ⟨component, tick⟩.

## API

Producer surface of the mtk toolkit for this entry: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.TickDecl`

signature — `ts/src/system.ts`

```
/** S-TICK: tick declaration – exact tick or jitter bracket. Tick
 * semantics is part of the model type, not a checker convention. */
export type TickDecl =
  | { readonly kind: "exact"; readonly period: QLike }
  | { readonly kind: "jitter"; readonly lo: QLike; readonly hi: QLike };
```

construction — `ts/tests/system-native.test.ts`

```
return sys.unwrap(
  sys.dtmc({
    name: "chain-3",
    outcomes: [
      { src: 0, dst: 0, prob: "1/3", reward: "0" },
      { src: 0, dst: 1, prob: "2/3", reward: "1" },
      { src: 1, dst: 2, prob: "1", reward: "5" },
      { src: 2, dst: 2, prob: "1" },
    ],
    initDist: [{ state: 0, prob: "1" }],
    tick: { kind: "exact", period: "1/50" },
  }),
);
```

The quoted fixture declares an exact tick; the composite fixture’s schedule assumption (S-HYBTIME) carries the jitter-bracket form.

### Rust `mtk_catalogue::system::TickDecl`

signature — `crates/mtk-catalogue/src/system/manifest.rs`

```
/// System Catalogue: Tick declaration – the composition-critical
/// counter-time vocabulary. A counter-time mechanism composed into
/// real time declares its tick as a timer mechanism whose reset
/// parameter is a point (**exact tick**) or a box (**jitter
/// bracket**). Tick semantics is part of the model type, not a
/// checker convention (the LunarLander pair is the standing price
/// demonstration: a factor 2.66 in certified ticks-to-funnel).
#[derive(Debug, Clone, PartialEq, Serialize, Deserialize)]
#[serde(rename_all = "snake_case")]
pub enum TickDecl {
  /// Exact tick: reset parameter a point.
  Exact { period: WitRat },
  /// Jitter bracket: reset parameter a box `[lo, hi]`.
  Jitter { lo: WitRat, hi: WitRat },
}
```

construction — `crates/mtk-catalogue/tests/common/mod.rs`

```
let m = MechanismBuilder::new()
  .outcome(OutcomeRow {
    src: 0,
    action: None,
    dst: 0,
    prob: r(1, 3),
    reward: Some(r(0, 1)),
  })
  .outcome(OutcomeRow {
    src: 0,
    action: None,
    dst: 1,
```

```

        prob: r(2, 3),
        reward: Some(r(1, 1)),
    })
    .outcome(OutcomeRow {
        src: 1,
        action: None,
        dst: 2,
        prob: r(1, 1),
        reward: Some(r(5, 1)),
    })
    .outcome(OutcomeRow {
        src: 2,
        action: None,
        dst: 2,
        prob: r(1, 1),
        reward: None,
    })
    .init_dist(0, r(1, 1))
    .tick(TickDecl::Exact { period: r(1, 50) })
    .finish();
presets::Dtmc::manifest(m)
    .expect("fixture conforms to the DTMC profile")
    .named("chain-3")

```

## 12.3 Static Systems

**The frame.** A value chosen once and never revised: the unknown constant of an estimation problem — a parameter picked demonically from a box and frozen for all time — and the token System of a colourless Petri net under the Bag former of section 12.17, where Bag over a point is the naturals with counting semantics. The bread-and-butter question is membership: which values the initial region admits, and what a surrounding composite may conclude from the box that bounds them.

**Profile.** Substrate only — state variables, unboxed or boxed parameters, interface, demonic initial region — with no dynamics family populated: the bottom of the manifest family; every other profile of this chapter populates families beyond it. At any dimension it is the zero-drift degenerate of the drift-only frame; at dimension zero it is the only dynamics-capable reading, because the zero drift vector there *is* the empty vector — a drift roster empty by dimension, not by omission. Time: continuous, trivially; the trajectory never moves.

**Semantics.** One convention is fixed here and consumed by everything downstream: absent dynamics denote a *frozen* carrier, never an unconstrained one. Records are constant paths valued in the initial region; the demonic initial face is the same box convention as the deterministic siblings — the denotation is the union over the region of per-point singletons — so the record set is the initial region, read as paths.

**Adequacy.** Definitional at this frame, and stated rather than mechanized: both routes of the square of Figure 12.1 name the constant records valued in the initial region — compilation contributes the initial row and the frozen-carrier convention, classical interpretation contributes the constant path at each admitted point, and there is no analysis between them to be wrong about. At positive dimension the same record set is carved by the drift-only rows of Problem 12.1 at  $f = 0$ ; at dimension zero the carrier is a single point. No dedicated mechanization is claimed: the frame's load-bearing content is the convention, not a theorem.

**Status.** Vocabulary and remedy, not yet certificate: no shipped certificate consumes the profile at this preview — it enters the inventory as the landing pad other entries point at. Production: presets in both languages construct the manifest (the API block below). The distinguishing shipped artefact is the refusal pairing: a drift-requiring preset meeting a zero-dimensional, substrate-only mechanism refuses with a remedy naming this profile, and the property suite checks that refusal's geometry — family absent, state roster empty, and the named remedy accepting. One name collision is worth disambiguating here: elsewhere in this chapter the graphical-model sub-frames are called static because they have *no internal time axis* (section 12.20); this profile has the time axis, and nothing moves along it.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (`crates/mtk-catalogue/src/system/`), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ ,  $\text{pop}$ , and profile conformance are defined in section 12.1.

$$\frac{}{\text{Static} : \text{System}} \text{S-STATIC}$$

The axiom of the manifest family: no dynamics family is consumed, and the formation data beyond the substrate  $\Sigma$  of section 12.1 (state variables, possibly none; parameters; interface; demonic initial region) is empty. Any populated dynamics family is a stray — the preset refuses it at any dimension.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.staticProfile`

signature — `ts/src/system.ts`

```
/** The static profile: substrate only – state space, parameters,
 * interface, demonic initial region; no dynamics families. The
 * initial condition is chosen demonically from the initial region
 * and then never moves: the zero-drift degenerate of the ODE profile
 * at any dimension, the only reading at dimension zero (where the
 * zero drift vector IS the empty vector), the token System of a
 * colourless Petri net under the Bag former, and the
 * unknown-constant System (a boxed parameter frozen for all time).
 * (`static` is a reserved word in module code, so the export carries
 * the profile suffix.) */
export const staticProfile = profileFactory("static");
```

The TS conformance corpus holds no construction through this factory at this preview — byte authority for the profile is the Rust corpus opposite; the factory takes the same init-object vocabulary as every other profile.

### Rust `mtk_catalogue::system::presets::Static::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```
preset!(
    /// System Catalogue: static profile – substrate only (state
    /// space, unboxed or boxed parameters, interface, demonic
    /// initial region), no dynamics families. The initial condition
    /// is chosen demonically from the initial region and then never
    /// moves: the zero-drift degenerate of the ODE profile at any
    /// dimension, and the only dynamics-capable reading at dimension
    /// zero, where the zero drift vector IS the empty vector. Two
    /// standing uses: the token System of a colourless Petri net
    /// under the Bag former (Bag over a point is the naturals with
    /// counting semantics), and the unknown-constant System (a value
    /// picked from a box, frozen for all time).
    Static, "static",
    req = [],
    allowed = [],
    extra = ok
);
```

construction — crates/mtk-catalogue/tests/builders.rs

```
let m = MechanismBuilder::new()
    .init(InitRegion::Box {
        region: BoxRegion { axes: vec![] },
    })
    .finish();
let sys = Static::manifest(m.clone()).unwrap();

// The unknown-constant reading: a boxed parameter axis, frozen
// for all time — substrate-only, so the same profile.
let frozen = MechanismBuilder::new()
    .param(0, Some("theta"), Some([r(1, 2), r(3, 2)]))
    .finish();
Static::manifest(frozen).unwrap();
```

The quoted span is the builders-suite happy path: the zero-dimensional token System (an initial box with no axes — the unique point of the zero-dimensional carrier) and the unknown-constant System (a boxed parameter, frozen for all time). The profile is also a refusal remedy: a drift-requiring preset meeting a zero-dimensional, substrate-only mechanism refuses with a pointer to this preset by name, and the refusal suite checks that the named remedy actually accepts.

## 12.4 Ordinary Differential Equations

**The frame.**  $\dot{x} = f(x)$  on a declared domain; the bread-and-butter questions are invariance, reach-avoidance, and Lyapunov decrease, plus validated enclosure of flows when the question is quantitative.

**Profile.** Drift only — the noise-free, jump-free corner of the manifest family. Carrier: the declared state variables over exact-rational box or simplex domains; polynomial right-hand sides native, non-polynomial ones by rationalization or by certified abstraction (the latter designed, not shipped). Openness, when wanted, enters as demonic input wires, not as a stochastic field. Time: continuous.

**Semantics.** Trajectory semantics — the drift-only specialization of the System semantics. Certificates about flows (tubes, flow maps) are licensed by once-per-format meta-theorems: the kernel checks inclusion-invariance sequents, and the reading of those sequents as statements about solutions is a named, stated obligation rather than kernel code. In the universe's terms: records over the classical site, read at the precise or possibilistic face of the denotation (Remark 9.22) according as inputs are absent or demonic.

**Adequacy.** The drift-only frame carries the catalogue's simplest instance of the square of Figure 12.1, and its content is easy to misjudge as vacuous: what compilation produces is not the textbook solution concept but *forward* constraint rows, and the square is the theorem that the two meet. Stated self-contained, at the working scale of an exam problem:

**Problem 12.1** (adequacy of the drift-only compilation). Fix a continuous  $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$  and  $x_0 \in \mathbb{R}^n$ . Records are paths  $y : \mathbb{R} \rightarrow \mathbb{R}^n$ ; only values at  $t \geq 0$  are observable. Say  $y$  satisfies the *compiled rows* when (i)  $y$  is continuous on  $[0, \infty)$  and at every  $t \geq 0$  has the forward derivative  $f(y(t))$  — the one-sided limit through times  $\geq t$  — and (ii)  $y(0) = x_0$ . Say  $y$  is a *classical solution* when  $y(0) = x_0$  and  $y$  is differentiable on  $[0, \infty)$  with  $\dot{y} = y \circ f$  (composition in diagrammatic order: first  $y$ , then  $f$ ) — two-sided at interior times, one-sided only at the corner  $t = 0$ . Show the two sets of records are equal, and show that the continuity clause in (i) cannot be dropped: exhibit a record with the correct forward derivative everywhere on  $[0, \infty)$  that solves nothing.

*Sketch.* Classical solutions satisfy the rows by restriction. Conversely the rows put  $y$  under the fundamental theorem of calculus twice: continuity of  $y$  (the record-class row) makes  $t \mapsto f(y(t))$  continuous, so the forward rows integrate — FTC for right derivatives — to the Picard identity  $y(t) = x_0 + \int_0^t f(y(s)) ds$ , the integral-equation form of the classical theory [46, 111]; then differentiating the integral at interior times gives the two-sided derivative. For the countermodel take  $f = 0$ ,  $x_0 = 0$ , and the step record  $y = k \mathbb{1}_{[t_0, \infty)}$  with  $k \neq 0$  and  $t_0 > 0$ : every forward derivative on  $[0, \infty)$  vanishes — right-continuity is free — but left-continuity fails at  $t_0$ , so the record-class row is load-bearing, not decorative.

In the universe’s terms: the two constraint families — the cell and the initial row — form a loose-arrow diagram at the possibilistic stratum, and the theorem says the diagram is isomorphic, by an invertible globular cell, to the support inclusion of the classical solution set: the same set-valued convention as the delay line (section 12.6), of which this square is the seam — the delay-line composite’s ODE-cell clause is this square’s row form at the field composed with the input signal, and the random-parameter frame (section 12.9) specializes it per draw. Three boundaries are stated rather than smoothed. Existence is not owed: the compiled atoms never exclude the vacuous model, blow-up in finite time ( $y = y^2$ ) can empty the solution set over  $[0, \infty)$  outright, and the constructive properness witness is the equilibrium record at a zero of the drift. Determinism is not a constraint-stratum fact: the atoms denote the solution *set*, and uniqueness enters as a theorem under the frame’s own declared-domain discipline — Lipschitz drift on the domain, solutions confined to it — consumed from the mechanized Grönwall interface, whose hypotheses are the forward rows verbatim: the community’s own uniqueness engine speaks constraint rows, not solution operators. And the connector consumes a completeness hypothesis on the carrier (the two FTC directions integrate), which the frame’s finite-dimensional state spaces satisfy; the bundling, the pinning theorems, and the wiring below do not consume it. The demonic initial face is the box convention of the mechanism declarations: its denotation is the union of the per-point solution sets, the deterministic frame’s shadow of the credal unions the stochastic squares use. The statement and both directions are mechanized, sorry-free, in the toolkit’s Lean tree (`lean/su-functor/`, module `SuFunctor.Adequacy.0de`): the connector is `isOdeSol_iff_integralCurve` — the classical side is the mechanized analysis library’s own integral-curve concept, not a private restatement — with the Picard form as `isOdeSol_iff_integral`, the invertible cell is `ode_adequacy` with the box face `ode_box_adequacy`, the pinning theorems are `odeSols_eq0n_of_lipschitz0nWith` and its global corollary, and the wiring into the semantic universe’s judgment (`su_ode_adequacy`) runs through the same transport layer as the sibling squares, with one possibilistic contrast stated deliberately: the zero law’s ideal point models every compiled presentation — support constraints never force realization, and the demand that the system realize anything at all is judgment-level content.

**Status.** Certification is in place twice over. Closed-loop controller certificates — an inverted-pendulum family, and a ladder re-verification of an aircraft collision-avoidance controller family — check through the unmodified kernel. The validated-enclosure species ladder de-trusts an established rigorous integrator: candidates from any proposer are re-founded on exact fixed-point inclusion checks, so the assurance story never rests on trusting interval arithmetic (the worked example of section 19.1). This frame also holds the inventory’s only cross-frame composition witness at this preview: an ODE plant wired to a discrete-time controller, with the assume-guarantee square transporting the certificate across the boundary and the composite checked by the unmodified kernel — every mutant of the composite refuses. Production: the toolkit’s producer surface constructs presentations in both languages and derives the Lie-derivative row  $\mathcal{A}V = \nabla V \cdot f$  symbolically from the presentation — the exact polynomial whose sign conditions the martingale-problem headlines of the stochastic siblings (sections 12.7 and 12.10) consume verbatim at their pure-drift face; derived and never trusted, the checker re-derives it. The double-integrator plant of the API block below is a committed standalone cross-language byte-identity vector whose conserved-energy zero the kit’s tests pin in closed form in both languages, and the kit is the jump-diffusion assembler at its degenerate face, the delegation warranted by the mechanized pure-drift degeneracy. Open: mechanism declarations exist as staged rows, but the ingestion path from rows to a checked model is not yet exercised end to end — a gap this frame shares with most of the list, named once here and cited below as “the ingestion gap”; and the enclosure ladder’s upper rungs rest on meta-theorems outside the kernel, an explicit trust boundary the species documentation states.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{\vec{x} \text{ declared state variables} \quad D : \overrightarrow{(\text{var}, \text{poly})} \text{ drift rows, each } \text{poly} \in \mathbb{Q}[\vec{x}]}{\text{ODE}(\vec{x}; D) : \text{System}} \quad \text{S-ODE}$$

Drift is the only dynamics family consumed. Openness, when wanted, enters as demonic input wires on *m.interface* — interface wires are substrate, never a stochastic family. At dimension zero the drift family cannot be populated at all — the roster is empty by dimension — and the preset refuses with a remedy naming the static profile (section 12.3).

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named *fx\_\** or *f.\** are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.ode`

signature — `ts/src/system.ts`

```
/** S-ODE: drift only (openness, if any, enters as demonic input wires
 * on the interface). Checks the family signature, then wraps into the
 * same manifest type as every other entry point – presets add
 * checking, never representation. */
export const ode = profileFactory("ode");

/** The derived ODE generator kit: the exact Lie-derivative
 * polynomial  $\dot{V} = \nabla V \cdot f$ . Derived, never trusted – the checker
 * re-derives it. */
export interface OdeGenKit {
  readonly gen: PolyWitness;
}

/** Derive the ODE generator kit from a mechanism declaration and a
 * certificate observable. Admission is the ODE profile's – diffusion,
 * jump, or killing rows refuse naming the stray family (those
 * presentations belong to `sdeGenKit` / `jdGenKit`); a parameter
 * roster is substrate and does not refuse, while drift naming a
 * parameter axis refuses at the arity fence (that presentation
 * belongs to `rodeGenKit`) – and the computed polynomial's identity
 * with the semantic generator at the drift-only face is mechanized
 * in the toolkit's Lean tree, whose ODE certificate theorems consume
 * the derived row's sign conditions verbatim. */
export function odeGenKit(
  init: MechanismInit,
  cert: Polynomial,
): Result<OdeGenKit, Refusal> {
  const raw = native.sysOdeGenKit(
    mechanism(init).nativeHandle,
    polyToNative(cert),
  ) as { kit: OdeGenKit } | { refusal: unknown };
  return "refusal" in raw
    ? refused(narrowRefusal<Refusal>(raw.refusal))
    : ok(raw.kit);
}
```

construction — `ts/tests/system-native.test.ts`

```
return sys.unwrap(
  sys.ode({
    name: "double-integrator",
    state: [
      { id: 0, name: "pos" },
      { id: 1, name: "vel" },
    ],
    interface: {
      inputs: [{ id: 0, name: "u" }],
      outputs: [{ id: 1, name: "y" }],
    },
  })
```

```

    drift: [
      { var: 0, poly: mono(2, 1, 1, "1") },
      { var: 1, poly: mono(2, 0, 1, "-1") },
    ],
  }},
);

```

**Rust** `mtk_catalogue::system::presets::ode::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```

preset!(
  /// System Catalogue: ODE profile — drift only (openness, if any,
  /// enters as demonic input wires on the interface).
  Ode, "ODE",
  req = [Drift],
  allowed = [],
  extra = ok
);

```

construction — `crates/mtk-catalogue/tests/common/mod.rs`

```

let m = MechanismBuilder::new()
  .state_var(0, Some("pos"))
  .state_var(1, Some("vel"))
  .interface(Interface {
    inputs: vec![WireDecl {
      id: 0,
      name: Some("u".to_owned()),
      sort: None,
    }],
    outputs: vec![WireDecl {
      id: 1,
      name: Some("y".to_owned()),
      sort: None,
    }],
  })
  .drift(None, 0, mono(2, 1, 1, r(1, 1)))
  .drift(None, 1, mono(2, 0, 1, r(-1, 1)))
  .finish();
presets::ode::manifest(m)
  .expect("fixture conforms to the ODE profile")
  .named("double-integrator")

```

The construction is the committed double-integrator golden vector (fixture ode, standalone byte authority; the same presentation serves the composite golden as its plant component), and it doubles as the generator kit's conserved-energy closed-form control ( $A(\text{pos}^2 + \text{vel}^2) = 0$ ); the kit's Rust face is `mtk_catalogue::system::ode_gen_kit`.

## 12.5 Partial Differential Equations

**The frame.** Evolution equations  $\partial_t u = F(u, \partial_x u, \partial_x^2 u, \dots)$ ; the bread-and-butter certified questions are energy dissipation and invariance.

**Profile.** A differential-polynomial mechanism over declared jet variables and a spatial domain — a sibling extension at the kernel's own level: integration-by-parts structure enters as exact polynomial-syzygy rows, pointwise nonnegativity as cone rows, and the checker gains nothing beyond jet arithmetic it already has. Time: continuous. Deterministic; the stochastic half is section 12.8's, which adds exactly one family to this profile.

**Semantics.** A solution-concept *run*g — classical, strong, or weak — with the semantic bridge (the finitely many analysis lemmas licensing the algebra-to-solutions reading) entering as named obligations, since largely discharged for this frame (see Status). This obligation discipline was established here first and the rest of the inventory inherits it.

**Adequacy (heat on a cyclic mesh).** Adequacy for a composed PDE says that compiling a spatial mesh of cells and walls, then denoting, agrees with interpreting the equation globally and including its solution set — and the first instance where the mesh is genuinely a *cover* is the heat equation on a circle, cut into three overlapping arcs. The cover is cyclic: the arcs meet in three collars, and the third collar closes the ring through the periodic identification. Cyclic covers are where local-to-global inference gets dangerous — Vorob’ev exhibited pairwise-consistent families of finite marginals over a three-cell ring with no joint law at all [235] — so the instance is chosen to make the mesh earn its consistency rather than inherit it.

**Problem 12.2** (heat on a cyclic mesh). Fix a diffusivity  $D$ , a circumference  $L$ , arc breakpoints  $0 < a < b < L$ , a collar half-width  $0 < \delta < L$ , and an open time window  $T$ . On the universal chart, the three arcs are  $I_1 = (-\delta, a + \delta)$ ,  $I_2 = (a - \delta, b + \delta)$ ,  $I_3 = (b - \delta, L + \delta)$ . A mesh record is a triple of cell fields  $(u_1, u_2, u_3)$ , and the compiled constraints are six: on each arc, the field is continuous, twice differentiable in space, and satisfies  $\partial_t u_i = D \partial_{xx} u_i$  pointwise (the cell rows);  $u_1 = u_2$  on  $I_1 \cap I_2$  and  $u_2 = u_3$  on  $I_2 \cap I_3$  at observed times (the chain walls); and  $u_3(x) = u_1(x - L)$  on the ring-closing collar (the wrap wall). Show that a record satisfies all six constraints if and only if there is a single  $L$ -periodic global solution of the heat equation agreeing with every cell field on its arc. Show moreover that the wrap wall is not implied by the rest: the linear field  $u_i(x, t) = x$  satisfies every cell row and both chain walls on all three arcs, and fails the wrap wall alone.

*Sketch.* ( $\Rightarrow$ ) Paste the two chain seams first: the piecewise field agrees with some cell field on a neighbourhood of every chart point, the walls supplying agreement across the collars, and the heat rows are germ-determined — differential operators are local — so the paste solves on the chart. Then periodize: the wrap wall is consumed exactly once, as the consistency identity of the periodic extension at the ring-closing collar, and locality carries the rows to the whole line. ( $\Leftarrow$ ) Clipping a global periodic solution to the arcs satisfies the cell rows by restriction, the chain walls because all three cells read one field, and the wrap wall by periodicity. No parabolic theory appears in either direction — no semigroup, no regularity, no maximum principle: the square lives at the record stratum, where gluing is descent plus locality.

In the universe’s terms: the six constraint families form a loose-arrow diagram of the thin double category of per-element constraints, walls and cells alike read at the possibilistic stratum, conjoined once at the mesh joint — and composition order is immaterial, since satisfaction of a conjunction reads through membership only. The theorem says the diagram is isomorphic, by an invertible globular cell, to the support inclusion of the global periodic solution set; as in the transport instance, no constraint forces mass, and the demand that the mesh realize anything is judgment-level, discharged constructively by the equilibria. The cyclic cover’s extra obligation is a *holonomy* constraint, carried as an ordinary reusable wall: the linear field — a perfectly good local solution family that fails to descend to the circle — passes every per-cell and pairwise-chain check and is refused by the wrap wall alone, and no global periodic field restricts to it. This is the two rings’ contrast made precise: the frustrated marginal ring fails invisibly, at the measure tier, where consistency of laws carries no global witness and the lawful credal denotation collapses to the bottom object; the heat ring’s obligations are record-tier, local, and visible as walls, its denotation is satisfiable, and local-to-global gluing is a theorem. The statement and both directions are mechanized, sorry-free, in the toolkit’s Lean tree (lean/su-functor/, module SuFunctor.Adequacy.HeatTorus): the ring glue is `heat_mesh_glues`, the invertible cell is `heat_adequacy`, the holonomy witness pair is `chainAtoms_dirac_lin` with `not_wrap_lin`, the interval control (cutting the ring trivializes the obligation) is `heat_chain_glues`, and the marginal-ring obstruction and its credal absorption are `vorobev_no_joint` and `credalCompile_vorobevGlue` in `SuFunctor.Adequacy.MarginalGlue`, with the two rings’ contrast packaged as a single statement, `heat_ring_glues_vorobev_ring_not`. Two strata are named separate, deliberately: with finitely many test rows in place of the pointwise rows, the compiled constraints are implied by solution-hood and do not pin it, the equivalence returning only in the mesh-refinement limit; and the exact-rational certificate stratum carries the dynamics as outward-rounded enclosures, never equalities —  $e^{-\lambda t}$  is transcendental at rational times, so the only exactly-propagated mode is the conserved mean. Neither stratum is mechanized; both carry recorded cost estimates — estimates, not available squares. The sign of  $D$  is consumed by neither direction of the square: certified decay, and with it the direction of well-posedness, is enclosure-stratum content, not a satisfaction clause.

**Adequacy (the initial face as a port).** The mesh square above keeps its time windows open — interior discipline; no statement mentions  $t = 0$ . The suite’s seventh square wires the initial condition as an *exposed port*: the initial face enters as a boundary trace along the window’s own filter — the field on each spatial

ray attains the port datum in the limit from inside the window, never as a row at an interior point — and three port atoms, one per arc, extend the six mesh atoms to nine. The ported square closes, still two-sided at the pointwise-record stratum. Its most important content is a deliberate absence: *feeding* the port — exhibiting, for a given datum, a global periodic solution attaining its trace — is a named definition, and the consistency discharge is conditional on a feed, because for general admissible data the feed *is* the heat semigroup on the circle [70]: enclosure-stratum content, cited and never mechanized — the heat analogue of the chain square’s Ionescu–Tulcea stratum, with the unconditional consistency theorem deliberately absent. The constructive floor is mechanized without any semigroup: equilibria feed constant data, and a single Fourier mode feeds a genuinely nonconstant datum — what the semigroup buys is only the limit over infinitely many modes for merely-continuous data. Compatibility conditions on the datum are *derived*, never assumed: the wrap wall plus the traces force the datum’s holonomy identity on the ring-closing collar — the delay line’s corner-condition lesson recurring one cover rung up — and periodicity of a global solution forces the same identity from the classical side. The face’s only new fee is the non-triviality of the window’s boundary filter — without it the traces are vacuous and the compatibility statements fail, so the fee is load-bearing — discharged for the concrete window. The sign of  $D$  remains nowhere, even at the port: backward heat feeds the same single mode, growing, so the record stratum still cannot see the direction of well-posedness — uniqueness of the fed solution, and its genuine failure backward, are enclosure-stratum business, cited with the semigroup. Mechanized, sorry-free, beside the mesh square (lean/su-functor/, module `SuFunctor.Adequacy.HeatTorusInit`): the invertible cell is `heat_init_adequacy`, the conditional consistency discharge is `heatInitAtoms_consistent_of_feed`, the derived wrap-compatibility pair is `initFace_wrap_compat` with its classical-side twin `IsHeatTorusSolInit.trace_wrap_compat`, the constructive floor is `portFeed_const` and `portFeed_mode` (with `modeDatum_ne_const`), and the filter fee’s discharge is `initFace_neBot`.

**Adequacy (solution sets on the mesh).** Where a single field glues, a *set* of fields need not: nonuniqueness enters the mesh as imprecision — each cell carrying a closed set of local solutions, its observable face the union of their graphs — and at that stratum the descent question splits cleanly in two. Descent of the closed sets themselves is exact: over any open cover of the window, closed subsets of the spacetime-value ambient correspond homeomorphically, in the Fell topology, to overlap-compatible families of closed subsets of the cells — a sheaf condition in equalizer form, demanding neither directedness nor finiteness of the cover — and the ring’s three arcs are its first working instance. What fails is citizenship transport. The witness is the integer orbit of the linear field — all period-translates at once, a closed set because the branch set is discrete. Its every clip is a union of cell-solution graphs; its clip family is overlap-compatible; it satisfies the set-level wrap wall (the orbit is invariant under the period shift, so the wall that refused the single linear field is blind to the full orbit); it is even a union of window-solution graphs. Yet it is the graph-union of no family of periodic solutions whatsoever: a global solution threading the tube is pinned to a single branch — continuity against a discrete branch set — and single branches do not close up. The gluing that one refusable wall purchased at the record stratum is purchasable by no pointwise wall at the record-set stratum: the missing datum is the pairing of branches across seams — which branch continues which around the ring, correspondence data subject to a cocycle condition — and forgetting exactly that labelling is the whole failure, since labelled families glue member by member through the record-stratum theorem. Consistency, by contrast, is free at this stratum: the top tube — every value at every point, maximal imprecision — is the graph-union of all constant equilibria and satisfies every wall, so the consistency obligation concentrates entirely on non-vacuous imprecision. And the failure remains detectable one stratum down, as consistency of a composed object rather than as any wall’s refusal: compiling the orbit tube to per-cell enclosure constraints and conjoining with the mesh’s own rows forces the empty model — the branch indices are frustrated around the ring by an integer cocycle, the seams forcing them equal and the wrap wall forcing a shift. All of it is mechanized, sorry-free, beside the heat module (lean/su-functor/, module `SuFunctor.Adequacy.SolutionSetMesh`): the descent equivalence is `FellClosedEqualizerHomeomorph` instantiated as `meshDescent`, the packaged witness is `setStratum_holonomy` with `orbitTube_not_torusTube`, the failure of local character is `not_isLocalLocusEq_torusTube`, the one-sidedness of the compiled square is `tubeAtoms_not_classical` against the forward cell `solset_forward_cell`, the free consistency witness is `isTorusTube_univ`, the labelled positive face is `labelled_ensembles_glue`, and the record-tier shadow is `orbit_enclosure_forces_zero`.

**Adequacy (the frame, at every mechanism).** The three squares above are instances — heat, with one operator hard-coded. The suite’s frame-level statement proves the mesh square once for *every* mechanism

of the formation rule, and in doing so isolates exactly what a solution concept owes the mesh: two lemmas.

**Problem 12.3** (the mesh square, at every mechanism). Let a mechanism assign to each of finitely many components a drift polynomial in the components' spatial jets through a declared order, and take as its pointwise rows: joint continuity of each component, spatial differentiability of each iterated derivative below the declared order in canonical-value form, and the drift equations — each component's time derivative equals its polynomial read on the jets. On the cyclic three-arc mesh, with the same six constraint families as the heat square, show: (a) the two *interface lemmas* hold uniformly in the mechanism — germ locality (agreement on an open rectangle transports the rows) and spatial homogeneity (translates of solutions solve at translated points); (b) for any solution concept satisfying the two lemmas, a mesh record satisfies all six constraints if and only if a single  $L$ -periodic global solution of the concept agrees with every cell field on its arc; (c) constants at roots of the drift's reaction structure satisfy the compiled conjunction, and  $1/2$  is not a root of Fisher–KPP's.

*Sketch.* (a) Locality is an induction on jet order — agreement on an open set transports every iterated derivative, pointwise on the set — and homogeneity an induction from the first-order translation identity, junk values included; neither consumes any property of the polynomial beyond its evaluation. (b) The forward direction is the heat square's paste-and-periodize argument verbatim, with the interface fields in place of the heat lemmas: the chain paste consumes locality alone, the ring-closing periodization additionally consumes homogeneity — locality buys the interval, homogeneity buys the holonomy leg. Backward is clipping. (c) The jet read of a constant is its value at order zero and zero above, so the drift equations reduce to the reaction structure's root condition; evaluating Fisher–KPP's reaction at  $1/2$  gives  $1/4 \neq 0$ .

The mechanized statement is parametric twice over. Over *mechanisms*: the heat square is re-derived as a specialization — the compiled atoms of the heat instance are the frame square's at the heat concept definitionally, and the heat rows are the jet rows of the declared second-order mechanism, so the instance's hard-coded operator and the formation rule's jet data present the same constraints — while viscous Burgers, Fisher–KPP, and a cross-coupled second-order pair receive their squares as one-line corollaries, with zero new inductions. Over *solution concepts*: a rung enters as data — its rows in germ form together with the named obligations the square consumes (locality, at weak rungs the partition-of-unity argument of the literature [70]; homogeneity; the strong-rung inclusion) — and every rung meeting them inherits the two-sided square, plus a one-directional cell from the pointwise rung's compiled mesh to its own, the solution-concept ladder's enclosure-shaped transfer. At the generality of the formation rule there is no canonical weak form — a fully nonlinear differential polynomial admits none, and weak formulations are per-structural-class — so the rung interface is the strongest true frame-level statement, with each class's community tie an instantiation obligation. Consistency is equilibrium-conditional at this level: heat and Burgers admit every constant, Fisher–KPP exactly two, and a mechanism without real equilibria defers non-vacuity to existence theory, the named separate stratum. The sign blindness of the heat square is now uniform: no statement consumes any property of the drift polynomial beyond evaluation. Mechanized, sorry-free, beside the heat module (`lean/su-functor/`, module `SuFunctor.Adequacy.Pde`): the concept-generic square is `LocalRows.mesh_adequacy`, the interface lemmas are `PdeAt.congr` and `PdeAt.comp_sub_const`, the frame square is `pde_adequacy`, the heat re-derivation is `heat_adequacy_of_mesh` with the jet-grain tie `heatAt_iff_pdeAt`, the instance corollaries are `burgers_adequacy`, `kpp_adequacy`, and `coupled_adequacy`, the rung ladder is `PdeRung` with `rung_adequacy` and `pde_rung_transfer`, the consistency witness is `pdeAtoms_consistent_of_equilibrium` with the non-equilibrium receipt `kpp_not_equilibrium_half`, and the semantic-universe wiring is `su_pde_adequacy`.

The suite also carries the *declared-data* face of the same statement (module `SuFunctor.Adequacy.PdeRows`): a row specification — state variables, jet declarations, sparse exponent-tuple drift rows over the positional index space `state ++ jets` — compiles into the formation rule's mechanism (`PdeRowSpec.toMechanism`), the compile provably reads no position beyond a row's declared width (`toMv_congr`, `toMechanism_congr_inhabited`), and the four instance mechanisms above are re-derived *from declared rows* as polynomial identities (`heatRowSpec_toMechanism` and `kin`, at the certified constants), so the squares and the semantic-universe wiring specialize to presented data with no new proof (`heat_rows_adequacy`, `su_pde_rows_adequacy`).

**Status.** Certification: four exact-rational artefacts — viscous Burgers energy dissipation at the sharp rate (every mutant of its battery refuses), a Fisher–KPP certificate that is the family's first to *need* a box constraint, and Kuramoto–Sivashinsky twice, checked by an independently implemented exact checker. To

our knowledge, exact-certified PDE dissipation bounds with replayable proof objects do not appear in the surveyed literature, whose own methods sections describe floating-point and semidefinite-programming foundations; this frame was also a not-covered cell in the 2023 SDCPN grading. The bridge lemmas, staged as named obligations when this catalogue was first graded, have since been largely discharged in mechanized form: axiom-clean Lean theorems now cover the classical licensing lemmas, the Fourier bridges, the energy laws at their sharp decay rates, uniqueness for viscous Burgers at the classical rung, and the weak-rung transfer of every certificate conclusion — the last consuming nothing beyond the solution-class definition, Parseval, and elementary iteration: a machine-checked confirmation that certificate soundness never rested on the hard existence theory. Representation and production: the toolkit constructs jet-grain presentations in both languages and derives the canonical differential-polynomial right-hand side from the declared rows (the producer face of the mechanized compile edge, shared with the stochastic sibling's kit, section 12.8); the viscous-Burgers mechanism at jet grain is a committed cross-language byte-identity vector, and the API block below quotes its receipted construction. Deliberately open: one comparison-principle lemma and the weak-rung energy-inequality variants of the fourth-order family, each small and well-scoped; classical existence itself — needed for non-vacuity, never for soundness; boundary-condition classes beyond the exercised torus and mean-zero settings; certificate artefacts for PDE mechanisms inside compositions (the mesh square above, Problem 12.2, carries the semantic square for the first such composition); and the ingestion gap.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (`crates/mtk-catalogue/src/system/`), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{J : \overrightarrow{\langle \text{base}, \alpha \rangle} \text{ jet variables} \quad \begin{array}{l} \vec{x} \text{ declared state variables} \\ D \text{ drift rows over the extended index space } (\vec{x}, J) \end{array}}{\text{PDE}(\vec{x}; J; D) : \text{System}} \text{ S-PDE}$$

Jet variables extend the polynomial index space (state variables first, jet variables after), each declaring its base field variable and spatial multi-index  $\alpha$ ; drift rows over that space are the differential-polynomial mechanism.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

```

The derived kit's Rust face is `mtk_catalogue::system::pde_gen_kit` — the canonical differential-polynomial right-hand side per field component at the extended index space, the producer face of the mechanized declared-data compile edge; the quoted TS construction is the committed viscous-burgers-jet golden vector's own presentation.

## 12.6 Delay Differential Equations

**The frame.** Delay differential equations  $\dot{y}(t) = f(y(t), y(t - \tau))$  with delay  $\tau > 0$  and a continuous history  $\varphi$  on  $[-\tau, 0]$ , in the classical sense of Hale–Verduyn Lunel [107]: solutions are continuous on  $[-\tau, \infty)$ , agree with the history, and satisfy the equation forward in time from  $t = 0$ . The textbook state space is the *history segment*  $y|_{[t-\tau, t]}$ , an element of the infinite-dimensional space  $C([-\tau, 0])$  — the feature that makes delay equations look like a new semantic species.

**Profile: none — a wiring pattern.** This frame adds no formation rule, no new mechanism family, and no new semantic species. A delay equation is a composite of inventory the catalogue already carries: an ODE cell (section 12.4) wired to an *ideal delay line* — the transport equation  $\partial_t u + c \partial_x u = 0$  on a segment of length  $c\tau$ , the simplest instance of the PDE frame (section 12.5)<sup>1</sup> — through three interface wires: a *load* wire placing the history on the line at time zero, an *inflow* trace wire pinning the upstream face to the cell's state, and an *outflow* tap reading the downstream face into the cell's vector field. The wires are directional in exactly the way the transport operator's dependence structure dictates: characteristics enter at the inflow and initial faces, which are the faces the wiring pins; the downstream face is read, never pinned. The infinite-dimensional history state is then nothing but the field on the spatial cell, read along characteristics — a record of a cell the universe already has, not a new kind of state.

**Adequacy.** The reduction is not an analogy; it is a theorem, mechanized end to end. Stated self-contained, at the working scale of an exam problem:

**Problem 12.4** (the delay line is a composite). Fix  $c, \tau > 0$ , a vector field  $f : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ , and a continuous history  $\varphi : [-\tau, 0] \rightarrow \mathbb{R}^n$ . On the cylinder  $[0, c\tau] \times [0, \infty)$ , say a triple  $(y, z, u)$  — an  $\mathbb{R}^n$ -valued path, a tap signal, and a field — satisfies the compiled constraints when: (i) along every characteristic  $s \mapsto (c(s - \zeta), s)$  of the cylinder, the field's trace is continuous with vanishing derivative on its window (the transport rows); (ii)  $u(x, 0) = \varphi(-x/c)$  (the load); (iii)  $u(0, t) = y(t)$  (the inflow); (iv)  $z(t) = u(c\tau, t)$  (the tap); and (v)  $y(0) = \varphi(0)$ ,  $y$  is continuous, and  $\dot{y}(t) = f(y(t), z(t))$  forward in time (the ODE cell). Show that  $(y, z, u)$  satisfies the compiled constraints if and only if there is a classical solution  $Y$  of the delay equation with history  $\varphi$  such that, on the composite's domains,  $y = Y$ ,  $z(t) = Y(t - \tau)$ , and  $u(x, t) = Y(t - x/c)$ . In particular the tap carries the state delayed by exactly  $\tau$ , and the spatial slice  $x \mapsto u(x, t)$  carries exactly the history segment  $Y|_{[t-\tau, t]}$ .

*Sketch.* ( $\Leftarrow$ ) Along each characteristic the coordinate  $t - x/c$  is constant, so the reparameterized read of  $Y$  is constant on each trace and the transport rows hold; the wire clauses are the definitional reads of  $Y$ . ( $\Rightarrow$ ) The one-variable mean value theorem pins each trace to its entry value — the inflow face for characteristics launched at  $\zeta \geq 0$ , the initial face for  $\zeta \in [-\tau, 0)$  — so the field is the concatenation of history and state read along characteristics (the method of characteristics [70], in its entirety); the tap then reads that concatenation at  $t - \tau$ , the ODE row becomes the delay equation, and the corner compatibility where the inflow face meets the initial face is precisely the initial condition  $y(0) = \varphi(0)$ . No stepwise construction appears: the correspondence is uniform in  $t$ , and the method of steps is an existence technique the equivalence never consumes.

In the universe's terms: the five constraint families — two cells and three wires, the wiring diagram read clause for clause — form a loose-arrow diagram of the thin double category of per-element constraints, each clause read at the possibilistic stratum (every record the model deems possible satisfies it); the theorem says this diagram is isomorphic, by an invertible globular cell, to the support inclusion of the classical solution set. The inclusion is set-valued because the square presupposes no uniqueness theory — solution sets play the role that credal sets play for the stochastic frames — and the per-solution face recovers the pointwise deterministic inclusion: each classical solution's point mass satisfies the compiled constraints. Unlike the stochastic squares,

<sup>1</sup> And the idealization of a real machine: the mercury acoustic delay-line memories of the earliest stored-program computers held their bits as waves in transit down a tube, read at the far end and re-injected at the near one — a store whose state is a field on a spatial segment, as the wiring pattern reads the history.

no constraint forces total mass: the possibilistic clauses are closed under sub-mass and mixtures, and the demand that the system realize anything at all is judgment-level content, discharged constructively at equilibria of the closed loop. The statement and both directions are mechanized, sorry-free, in the toolkit's Lean tree (`lean/su-functor/`, module `SuFunctor.Adequacy.DelayLine`): the record-level equivalence is `composite_iff_dde`, the invertible cell is `delayline_adequacy`, the delay identity is `outflow_delay`, and the history-segment identification is `field_slice_is_history`. Where the PDE frame's semantic bridge is staged as named obligations, this instance's left edge is total: characteristics reduce it to elementary one-variable calculus, which is what makes the delay line the transport instance whose adequacy square closes two-sided today. Dynamics enter as constraint rows, never as a solution operator: the shift semigroup the functional-analytic literature takes as primitive is *derived* content of this left edge.

**Status.** The wiring-pattern theorem and the square are mechanized as above. Certification inherits the PDE frame's machinery in its exactly-solvable corner: for rational  $c$ ,  $\tau$ , and piecewise-polynomial data with rational breakpoints, solution-by-characteristics is exact rational arithmetic — the field's natural finite presentation is its Bernstein coefficient vector in the characteristic coordinate, on which transport acts as the identity (the read head moves; the tape stands still), and endpoint traces are endpoint coefficients. Multiple discrete delays are multiple transport cells in parallel, a corollary of the same pattern. Deliberately open: an ingestion profile for the wiring pattern (the chapter's recurring lesson applies here too); Lyapunov–Krasovskii functionals read as cell-wise energies with flux cancellation at the wires, which is designed, not built; and state-dependent or distributed delays, which leave the ideal-line instance and are out of scope.

No formation rule accompanies this section: that absence is the section's content.

## 12.7 Stochastic Differential Equations

**The frame.**  $dX = f(X)dt + \sigma(X)dW$ ; certified questions are reach-avoidance and invariance in probability, via supermartingale arguments on the generator. The one-dimensional Ornstein–Uhlenbeck process  $dX = -Xdt + \frac{1}{2}dW$  is the frame's harmonic oscillator: the construction quoted in the API block below, and the first shipped certificates' subject (see Status).

**Profile.** Drift plus diffusion. Rank-one noise populates a single diffusion column; correlated multi-driver noise populates one exact-rational  $\sigma$  column per independent Brownian driver, with the covariance  $a = \sum_k \sigma^k (\sigma^k)^\top$  *derived, never stored* — a representation choice that keeps the checker's inputs primitive. State-dependent  $\sigma(x)$  is representable (the columns are polynomials). Time: continuous.

**Semantics.** The extended-generator rung: certificates are polynomial inequalities on  $\mathcal{A}V = f \cdot \nabla V + \frac{1}{2} \sum_{ij} a_{ij} \partial_{ij} V$ , and the reading of an accepted sequent as a probability bound rests on staged Dynkin and optional-sampling hypotheses — named, textbook-standard for polynomial coefficients on compacts, and outside the kernel. The bound so read is certificate membership in the denotation's defining infimum, on the per-element route whose continuous-time scope section 9.5 prices. The Adequacy paragraph below discharges the staged hypotheses for solutions presented by their martingale problem; what stays staged is scoped to presentations that are not.

**Adequacy.** The square for this frame closes at the community's own solution concept — not the Itô integral, which the mechanized library deliberately does not assume, but the *martingale problem* [69, 227]:  $X$  solves the martingale problem for  $\mathcal{A}$  when, for every admissible test observable  $V$ , the compensated process  $V(X_t) - \int_0^t (\mathcal{A}V)(X_s) ds$  is a martingale. Weak Itô solutions and martingale-problem solutions coincide; that equivalence is the community's own theorem, cited here as the licence and deliberately not re-proved (it needs the stochastic integral, which is absent from the underlying mathematics library at the pinned version — a strong-solution left edge waits on upstream stochastic integration). For the compiled fragment the identification is definitional in the literature itself: polynomial diffusions are *defined* by the martingale problem with polynomial test functions [78]. Stated self-contained:

**Problem 12.5** (the martingale-problem square). Fix an SDE profile with polynomial coefficients — drift  $f$ , diffusion columns  $\sigma^k$ , jump rate  $\lambda$  with reset  $g$  — a closed working domain  $D$ , and a certificate polynomial  $V$  with exact rational coefficients. Suppose a process  $X$ , confined to  $D$ , solves the stopped martingale problem for the profile’s integro-differential generator  $\mathcal{A}$ , and the checker’s own compiled row holds: the exact-rational polynomial  $\mathcal{A}V$ , computed symbolically from the presentation, evaluates  $\leq 0$  everywhere on  $D$ , with  $V \geq 0$  on  $D$  and  $V \geq 1$  on a bad set  $B$ . Show that along every monotone sampling grid  $\tau$ ,  $\Pr(\exists k, X_{\tau_k} \in B) \leq \mathbb{E}[V(X_{\tau_0})]$ .

*Sketch.* Two statics identify the formal with the analytic: the Fréchet derivative of polynomial evaluation is the formal gradient — at order one, and, instantiated at each first partial, at order two — so the triple  $(V, \nabla V, \nabla^2 V)$  of exact-rational row data enters the martingale problem as a lawful  $C^2$  test datum; and evaluating the symbolically computed generator equals the semantic generator at that datum. The compensated certificate process is then a martingale whose compensator has nonpositive density along the confined path, so  $V(X_t)$  is a continuous-time supermartingale — Dynkin’s formula *derived* from the presentation, not assumed — and Ville’s inequality [234] along the sampled grid gives the bound.

The point of the square is what it retires: the staged Dynkin and optional-sampling hypotheses of the Semantics paragraph are, for martingale-problem-presented solutions, theorems, and the per-model residue is being a solution — the community’s own object — plus the per-datum integrability provisos, which are the textbook’s standing assumptions for unbounded test functions. The boundaries, stated as such: verdicts are on the sampled grid (the continuum-time supremum needs almost-sure path regularity, which stays with the constructor); well-posedness of the martingale problem is not claimed, exactly as the ODE square proved no Picard existence; and unlike this chapter’s discrete squares the transport here is one-directional — community semantics to certified verdict — with no invertible-cell claim at the path-law level. The statement and the discharge are mechanized, sorry-free, in the toolkit’s Lean tree (`lean/qtsl-aux/`, modules `QtslAux.SdeGenerator`, `QtslAux.SdeGeneratorPoly`, `QtslAux.SdeMartingaleProblem`): the solution concept is `MpSolution` (stopped/confined, generator-as-pairs form), the derived continuous-time supermartingale is `supermartingale_of_gen_nonpos`, the discharge of the Dynkin class field is `MpSolution.toSdeDynkinVille`, the compilation splice is `genPoly_eval_eq_generator`, the order-1/2 statics are `isC2Fn_poly`, and the compiled headline is `mp_avoid_row_of_genPoly` with its deterministic-start form `mp_avoid_init_of_genPoly`, exercised end-to-end by a zero-dynamics control (`mp_control`).

**Status.** Certification is in place at three scales: the one-dimensional Ornstein–Uhlenbeck certificates (the Hessian term present in the checked sequents); the same second-order term running inside jump-diffusion and hybrid composites (sections 12.10 and 12.16); and an encounter-scale correlated-noise family with the cross-term Hessian certified over two- and three-dimensional simplicial covers. The correlated family carries the frame’s signature results: a refusal witness for the decorrelated misreading of the same system, with the cross-term’s contribution in closed form, and a certified anisotropic bound pair — 0.242 against 0.828 at equal Euclidean distance — quantifying exactly what correlation is worth. Representation and production: the noise declarations are shipped theory rows, the correlated systems exist as instance rows, and the toolkit’s producer surface constructs presentations in both languages and derives the generator polynomial symbolically from the presentation — the exact computation whose identity with the semantic generator, at the pure-diffusion face, is the Adequacy paragraph’s mechanized splice; derived and never trusted, the checker re-derives it. The API block below quotes receipted constructions, and a correlated two-dimensional presentation — one shared driver loading both coordinates, so the cross term is live in the derived covariance — is a committed cross-language byte-identity vector whose generator the kit’s tests pin in closed form, against its decorrelated misreading. Open: state-dependent  $\sigma$  at  $n \geq 2$  (fully representable and derivable, but no shipped certificate exercises it yet); the imprecise denotation exercised as a certificate; the ingestion gap.

**SPDEs.** No longer an open flank: stochastic PDEs have their own entry (section 12.8). The road ran through the deterministic PDE machinery as promised — at the moment rungs, a stochastic certificate is the deterministic row stack plus a single Itô-correction row.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset

signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{\vec{x} \text{ declared state variables} \quad D \text{ drift rows} \quad N \text{ a noise presentation}}{\text{SDE}(\vec{x}; D; N) : \text{System}} \quad \text{S-SDE}$$

$$N ::= \text{diffusion}(\overline{\langle \text{var}, \text{poly} \rangle}) \mid \text{noise}(\sigma^1, \dots, \sigma^K)$$

Exactly one noise presentation, by the grammar rather than by a side condition: diffusion is the single-column form, noise the per-driver sigma-column form (one exact-rational polynomial column per independent Brownian driver); the covariance  $a = \sum_k \sigma^k (\sigma^k)^\top$  is derived, never stored.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named fx\_\* or f.\* are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript system.sde

signature — ts/src/system.ts

```
/** S-SDE: drift + diffusion (single-column) XOR noise (multi-driver
 * sigma columns; the covariance is derived, never stored). */
export const sde = profileFactory("sde");

/** The derived SDE generator kit: the exact generator polynomial
 *  $\mathcal{V} = \nabla V \cdot f + \frac{1}{2} \text{tr}(a \cdot \text{Hess } V)$ , the covariance  $a = \sum_k \sigma^k (\sigma^k)^\top$ 
 * derived from the presented columns, never stored. Derived, never
 * trusted — the checker re-derives it. */
export interface SdeGenKit {
  readonly gen: PolyWitness;
}

/** Derive the SDE generator kit from a mechanism declaration and a

 * killing rows refuse naming the stray family (those presentations
 * belong to `jdGenKit`) — and the computed polynomial's identity
 * with the semantic generator at the pure-diffusion face is
 * mechanized in the toolkit's Lean tree. The shared stratum fences
 * (single implicit mode, no transcendental terms) come back as
 * refusals naming their geometry. */
export function sdeGenKit(
  init: MechanismInit,
  cert: Polynomial,
): Result<SdeGenKit, Refusal> {
  const raw = native.sysSdeGenKit(
    mechanism(init).nativeHandle,
    polyToNative(cert),
  ) as { kit: SdeGenKit } | { refusal: unknown };
  return "refusal" in raw
    ? refused(narrowRefusal<Refusal>(raw.refusal))
    : ok(raw.kit);
}
```

construction — ts/tests/system-native.test.ts

```

return sys.unwrap(
  sys.sde({
    name: "ou-1d",
    state: [{ id: 0, name: "x" }],
    drift: [{ var: 0, poly: mono(1, 0, 1, "-1") }],
    diffusion: [{ var: 0, poly: constant(1, "1/2") }],
    init: { kind: "point", coords: [BIG] },
  }),
);

```

**Rust** `mtk_catalogue::system::presets::Sde::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```

preset!(
  /// System Catalogue: SDE profile – drift + diffusion
  /// (single-column) or noise (per-driver sigma columns; the
  /// covariance is derived, never stored).
  Sde, "SDE",
  req = [Drift],
  allowed = [Diffusion, Noise],
  extra = |m| diffusion_xor_noise("SDE", m)
);

```

construction — `crates/mtk-catalogue/tests/common/mod.rs`

```

let big = WitRat::new(
  "1234567890123456789012345678901234567890"
  .parse::<BigInt>()
  .unwrap(),
  BigInt::from(7u8),
);
let m = MechanismBuilder::new()
  .state_var(0, Some("x"))
  .drift(None, 0, mono(1, 0, 1, r(-1, 1)))
  .diffusion(None, 0, constant(1, r(1, 2)))
  .init(InitRegion::Point { coords: vec![big] })
  .finish();
presets::Sde::manifest(m)
  .expect("fixture conforms to the SDE profile")
  .named("ou-1d")

```

The multi-driver presentation (per-driver sigma columns) is the corpus's committed correlated-2d golden vector (fixture `sde_noise`, whose derived cross term the generator-kit tests pin in closed form); the generator kit's Rust face is `mtk_catalogue::system::sde_gen_kit`.

## 12.8 Stochastic Partial Differential Equations

**The frame.** Stochastic evolution equations  $du = F(u, \partial_x u, \partial_x^2 u, \dots) dt + dW_Q$ , with  $W_Q$  a  $Q$ -Wiener process over the declared spatial domain; the certified questions are expected-energy dissipation to a noise floor, absorbing balls, and probability bounds on energy excursions.

**Profile.** The deterministic jet mechanism plus a declared noise spectrum: finitely many explicit driver shapes — exact-rational combinations of the domain's orthonormal Fourier basis, one amplitude column per driver — and a required tail form in one of three shapes (zero, a rational trace bracket, or declared-divergent), so the covariance's trace is derived, never stored, and a spectrum without a declared tail is refused rather than read as zero. Amplitude columns are constants at this preview (additive noise), but their declared type is a polynomial over the jet space, so multiplicative noise is a fence-lift rather than a schema change. Time: continuous.

**Semantics.** The stochastic solution-concept rungs, weakest first: the expected-energy class (the inhomogeneous inequality with the trace of  $Q$  as its forcing constant), the compensated-supermartingale form (horizon-tagged), and the mode-law rung where explicit Ornstein–Uhlenbeck second-moment trajectories live. Every stochastic-analysis fact is a named obligation behind a class field with stated discharge routes — no theorem below the docstring mentions a stochastic integral — extending the staging discipline section 12.5 established.

**Status.** Certification: five exact-rational artefacts — stochastic Burgers and stochastic heat moment certificates (the deterministic rows carried verbatim, the Itô correction docked as one constant row; the heat floor  $\text{tr}(Q)/2\nu = 13/10$  exact, with a deliberately sharp width-zero instance) and two stochastic Kuramoto–Sivashinsky absorbing balls that embed and replay their deterministic siblings byte-identically before any stochastic row is added. All five carry probability rows: a horizon-tagged supremum bound of Kushner’s classical shape [147], Chebyshev on certified variances, and an exponential-compensation row strictly sharper at both registered points. Mutant batteries assert rejection messages, and witnesses realizing the noise are checker-required, so a green moment bound cannot be vacuously noise-silent. The jet-level declaration now has its proof-layer face: spectrum declarations with the required tail carry mechanized derived-covariance data (module `SuFuctor.Adequacy.PdeRows`: the explicit trace by Parseval with per-element grouping, the q-table diagonal with trace-equals-summed-diagonal, and the certified heat spectrum’s  $\text{tr}(Q) = 13/50$ ,  $q_1 = 1/5$ ,  $q_2 = 3/50$  recomputed by theorem), and the plain-trace consumer is total-or-refusing — a declared-divergent tail refuses structurally (`plainTrace_divergent_none`), never defaulting to zero. Representation and production: the toolkit’s producer surface now carries the derived-kit sibling of that proof layer, shared with section 12.5 — from a declared presentation the kit derives the canonical differential-polynomial right-hand side (the compile edge’s producer face) and, from the spectrum, the q-table diagonal, the trace as the summed diagonal, the plain-trace enclosure (structurally refused on a divergent tail, in both languages), and the dissipation floor  $\text{tr}(Q)/2\nu$  exactly where the presentation exhibits it — transport terms and mean-mode mass forfeit the floor rather than have it guessed; derived and never trusted, the checker re-derives every row. The kit’s tests recompute the certified constants from the committed golden vector’s own presentation, and the deterministic sibling (viscous Burgers at jet grain) is now itself a committed cross-language byte-identity vector. Deliberately open: trace-class tails (declaration vocabulary without a certified instance); the cylindrical mode-resolved variant; multiplicative noise; the Fourier mode-projection semantics (the compile-for-semantics leg, a named obligation at the Lean stratum); composition.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{J : \overrightarrow{\langle \text{base}, \alpha \rangle} \text{ jet variables} \quad \overrightarrow{\vec{x}} \text{ declared state variables} \quad D \text{ drift rows over } (\vec{x}, J) \quad N = (\overrightarrow{\langle \text{shape}, \text{amp} \rangle}; \tau) \text{ a noise spectrum}}{\text{SPDE}(\vec{x}; J; D; N) : \text{System}} \quad \text{S-SPDE}$$

$$\tau ::= \text{zero} \mid \text{traceBracket}(T_{\text{lo}}, T_{\text{hi}}) \mid \text{divergent}$$

The jet families are section 12.5’s, verbatim; the noise spectrum adds exactly one family. Each driver is a spatial shape (an exact-rational combination of the domain’s orthonormal Fourier basis) with an amplitude column; the tail form  $\tau$  is required by the grammar rather than by a side condition, so a spectrum without a declared tail is unrepresentable here and refused at preset admission in the toolkit. The covariance  $Q = \sum_j \text{shape}_j \text{shape}_j^*$  (plus the declared tail) and its trace are derived, never stored; a consumer needing the plain trace refuses a divergent tail.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s

shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## TypeScript system.spde

signature — ts/src/system.ts

```
/** S-SPDE: the PDE families plus a noise spectrum – Fourier-shape
 * driver rows (`noiseDrivers`) and a REQUIRED tail form
 * (`noiseTail`: zero XOR traceBracket XOR divergent). A spectrum
 * whose tail was never declared refuses here – never read as zero;
 * the covariance and its trace are derived, never stored. */
export const spde = profileFactory("spde");

  )
  .noise_tail(TailForm::Zero)
  .finish();
Spde::manifest(spde).unwrap();

```

The tail form is the spectrum's required member: the corpus's `spde_missing_tail_refused_never_read_as_zero` sibling exercises the admission refusal, and the divergent-tail plain-trace refusal is witnessed in `plain_trace_derived_never_stored`. The derived kit's Rust face is `mtk_catalogue::system::spde_gen_kit`: the  $q$ -table diagonal, the explicit trace as the summed diagonal, the plain-trace enclosure (structurally refused on a divergent tail), and the dissipation floor  $\text{tr}(Q)/2\nu$  exactly where the presentation exhibits it — the kit's tests recompute the reference constants ( $q_1 = 1/5$ ,  $q_2 = 3/50$ , trace  $13/50$ , floor  $13/10$ ) from the committed golden vector's own presentation.

## 12.9 Random Differential Equations

**The frame.** An ODE or PDE whose parameters  $\theta$  are drawn from a declared uncertainty set; the certified question is a property *uniform* over the set.

**Profile.** Drift plus a boxed parameter axis: the parameter is one more coordinate of the region, constant along trajectories. Disturbance semantics: uniform over the box — the  $\forall\theta$  leg is carried entirely by the region, not by any new machinery. Time: continuous.

**Semantics.** Per- $\theta$  trajectory semantics — each theorem a one-line specialization of the ODE semantics seam, and that one-line-ness is the measured content of the claim that the kernel’s cone treats parameter boxes natively. Uniformity over the box is, in the universe’s terms, a credal body — the possibilistic face over the box-indexed trajectory family (Remark 9.22) — and the  $\forall\theta$  verdict is its lower prevision (Definition 9.21).

**Status.** Certification: a damped oscillator  $\dot{x} = v$ ,  $\dot{v} = -x - \theta v$  with damping boxed  $\theta \in [1/4, 1]$  carries a barrier decrease  $\dot{V} \leq -\frac{1}{8}(x^2 + v^2)$  on an annulus, uniformly over the box, as one polynomial row family — checked, round-tripped through the wire format, with refusal probes on both producer and checker sides, and a mechanized per- $\theta$  semantics layer. This frame was priced as nearly free before it was built, and building it confirmed the price: the thesis’s own  $\forall\theta$  property form is RODE-shaped. Production: the toolkit’s producer surface constructs the boxed-parameter presentation in both languages, and the damped oscillator itself is a committed cross-language byte-identity vector, the parameter family’s first. The kit derives the state  $\times$  parameter generator row symbolically at the product index space, with derivatives over state axes only ( $\dot{\theta} = 0$ : a  $\theta$ -only observable is conserved, by test). Its tests pin  $\mathcal{A}(x^2 + v^2) = -2\theta v^2$  in closed form in both languages — one polynomial over the product space is the whole  $\forall\theta$  row family — and a collapse differential checks that a  $\theta$ -free drift derives exactly the ODE kit’s polynomial. Open: the mechanism as ingested rows (the ingestion gap); a fixture nonlinear in  $\theta$ ; and the RPDE side, which waits on section 12.5’s bridges.

**Adequacy.** The square for this frame is deliberately slight, and the slightness is itself the certified content: the community’s solution concept for random ODEs is *pathwise* — for each realization  $\theta$ , a classical solution of the  $\theta$ -instance, analyzed with deterministic calculus [109] — so the per-draw connector, square, and uniqueness theorems are the ODE square of section 12.4 at the drawn drift  $f_\theta$ , consumed verbatim rather than re-proved. What remains is the box. Stated self-contained:

**Problem 12.6** (the boxed-parameter square). Fix a drift family  $f : \Theta \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ , continuous in the state at each draw in a parameter box  $P \subseteq \Theta$ , and  $x_0 \in \mathbb{R}^n$ . Records are paths  $y : \mathbb{R} \rightarrow \mathbb{R}^n$ ; the compiled constraints are the initial row and the *boxed cell* — some draw  $\theta \in P$  drives  $y$ ’s forward rows. Show the compiled records are exactly  $\bigcup_{\theta \in P} S_\theta$ , where  $S_\theta$  is the classical solution set of the  $\theta$ -instance; show the same for the rectangle with both boxes open — the initial row replaced by an initial box  $B \subseteq \mathbb{R}^n$  — denoting  $\bigcup_{\theta \in P} \bigcup_{x \in B} S_{\theta,x}$ , with  $S_{\theta,x}$  the  $\theta$ -instance’s solution set from  $x$ ; and show the polarity of the box matters: over the empty box the compiled body is empty, while a uniform-verdict reading — intersection over draws — would admit every record.

*Sketch.* Intersecting with the initial row distributes into the parameter union, and each summand is the ODE square at  $f_\theta$ ; the rectangle composes the parameter union with the ODE square’s initial-box identity, one draw at a time; the empty union is empty, the empty intersection is everything.

The polarity is easy to get backwards. The compiled *body* over the box is a union — existential in  $\theta$ , the same demonic convention as the initial box — while the certified uniform-over- $\theta$  property of the Semantics paragraph above is the opposite polarity: a verdict over the whole box-indexed family, the lower prevision of Remark 9.22, living at the judgment, never as an intersection body. Uniqueness enters per draw with a certificate-shaped hypothesis — a single Lipschitz constant uniform over the box pins every draw in it, the semantics shadow of a certificate stated as one row family over state and parameter. The statement and both directions are mechanized, sorry-free, in the toolkit’s Lean tree (lean/su-functor/, module SuFunctor.Adequacy.Rode): the per-draw connector and square are `isRodeSol_iff_integralCurve` and `rode_draw_adequacy` (one-line specializations, stated as such), the union face is `rode_adequacy` with the

rectangle `rode_box_adequacy`, the uniform-constant pinning is `rodeSols_eq0n_of_lipschitz0nWith`, and the wiring into the semantic universe's judgment (`su_rode_adequacy`) runs through the same transport layer as the sibling squares, with the zero-law contrast holding at every box including the empty one — the infeasible frame denotes a bottom body, never an absence of models. The completeness hypothesis enters exactly where the ODE connector is consumed, nowhere else.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (`crates/mtk-catalogue/src/system/`), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ ,  $\text{pop}$ , and profile conformance are defined in section 12.1.

$$\frac{\Theta : \text{ParamDecl} \quad \exists p \in \Theta. p.\text{bounds} \neq \perp \quad D \text{ drift rows, each } \text{poly} \in \mathbb{Q}[\vec{x}, \Theta]}{\text{RODE}(\vec{x}; \Theta; D) : \text{System}} \text{ S-RODE}$$

$\vec{x}$  declared state variables

A boxed parameter (`bounds = [lo, hi]`, `exact`) is the  $\forall\theta$  axis; an unboxed parameter is a plain named constant, which is why the existential premise demands at least one box.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.rode`

signature — `ts/src/system.ts`

```
/** S-RODE: drift + a boxed parameter axis (disturbance: parameter
 * box, uniform-over- $\theta$ ). */
export const rode = profileFactory("rode");

/** The derived RODE generator kit: the exact Lie-derivative
 * polynomial  $\dot{V} = \sum_i \partial_{iV} \cdot f_i$  over the product index space
 * `state ++ params` (parameters in declaration order after the state
 * roster), state axes only — parameters are constant along
 * realizations, so no parameter-derivative term exists, and one
 * polynomial in state  $\times$  parameter is the whole  $\forall\theta$  row family.
 * Derived, never trusted — the checker re-derives it. */
export interface RodeGenKit {
  readonly gen: PolyWitness;
}

/** Derive the RODE generator kit from a mechanism declaration and a
 * certificate observable (read at the product arity — a certificate
 * may itself name the parameter axes, the family-certificate face).
 * Admission is the RODE profile's — an unboxed-only roster refuses
 * as `noBoxedParam`, and a drift row addressed past the state roster
 * refuses naming the row (a parameter has no evolution row). */
export function rodeGenKit(
  init: MechanismInit,
  cert: Polynomial,
): Result<RodeGenKit, Refusal> {
  const raw = native.sysRodeGenKit(
```

```

        mechanism(init).nativeHandle,
        polyToNative(cert),
    ) as { kit: RodeGenKit } | { refusal: unknown };
    return "refusal" in raw
    ? refused(narrowRefusal<Refusal>(raw.refusal))
    : ok(raw.kit);
}

```

construction — ts/tests/system-native.test.ts

```

return sys.unwrap(
  sys.rode({

```

## Rust mtk\_catalogue::system::presets::Rode::manifest

signature — crates/mtk-catalogue/src/system/presets.rs

```

preset!(
  /// System Catalogue: RODE profile – drift + a boxed parameter
  /// axis (disturbance: parameter box, uniform-over-θ).
  Rode, "RODE",
  req = [Drift, Params],
  allowed = [],
  extra = |m| {
    if m.params.iter().any(|p| p.bounds.is_some()) {
      Ok(())
    } else {
      Err(Refusal::NoBoxedParam { profile: "RODE" })
    }
  }
);

```

construction — crates/mtk-catalogue/tests/common/mod.rs

```

let vdot = Poly {
  vars: 3,
  terms: vec![
    PolyTerm {
      exps: vec![1, 0, 0],
      coeff: r(-1, 1),
    },
    PolyTerm {
      exps: vec![0, 1, 1],
      coeff: r(-1, 1),
    },
  ],
};
let m = MechanismBuilder::new()
  .state_var(0, Some("x"))
  .state_var(1, Some("v"))
  .param(0, Some("theta"), Some([r(1, 4), r(1, 1)]))

```

```

    .drift(None, 0, mono(3, 1, 1, r(1, 1)))
    .drift(None, 1, vdot)
    .finish();
presets::Rode::manifest(m)
    .expect("fixture conforms to the RODE profile")
    .named("damped-oscillator")

```

The construction is the committed damped-oscillator golden vector (fixture rode — the parameter family’s first golden bytes: drift over the product index space  $state ++ params$ , damping boxed  $\theta \in [1/4, 1]$ ), and it doubles as the generator kit’s closed-form control ( $\mathcal{A}(x^2 + v^2) = -2\theta v^2$  — one polynomial in state  $\times$  parameter is the whole  $\forall \theta$  row family); the kit’s Rust face is `mtk_catalogue::system::rode_gen_kit`.

## 12.10 Jump-Diffusion

**The frame.** Continuous drift and diffusion punctuated by Poisson-rate jumps; certified questions are ruin and reach-avoidance bounds through the extended generator with its jump term.

**Profile.** All three field families at once — drift, diffusion, and jump legs — on one mechanism, plus an optional killing family. Each jump row is one leg: a polynomial rate paired with a reset kernel, either a single polynomial reset (the Dirac form) or a finite mixture of weighted polynomial resets, with an optional reset-image box. Mixture weights may total *below* one: a sub-stochastic kernel is lawful by design, the mass deficit being killing (the standard convention for jump kernels of total mass below one [60]); a row presenting both kernel forms at once is refused, naming the row. Disturbance: Brownian drivers plus finite-activity jumps. Time: continuous, with jumps as events in real time; per-execution jump counters are bookkeeping, never a composition base.

**Semantics.** The extended generator  $\mathcal{A}V = fV' + \frac{\sigma^2}{2}V'' + \lambda(g \circ V - V)$ , composed from the same shipped summands the pure-diffusion and pure-jump frames use, with no new checker machinery — each degenerate case asserts its reduction to the shipped frame. Finite-activity hypotheses are named; the bridge set is the diffusion frame’s plus an Itô–Lévy step.

**Adequacy (generator face).** The Semantics paragraph’s composition claim — the generator assembled from the shipped summands, each degenerate case asserting its reduction — is mechanized at the frame’s full profile generality, and the identity holds with *no side conditions*. Stated self-contained:

**Problem 12.7** (the generator splice, at full profile generality). Fix a polynomial jump-diffusion presentation: drift  $f$ , diffusion columns  $\sigma^k$ , a killing rate  $c$ , and finitely many jump legs, each a polynomial rate  $\lambda_\ell$  paired with a finite sub-stochastic mixture of polynomial resets  $(w_{\ell i}, g_{\ell i})$ . Write  $T_{\mu_\ell}V = \sum_i w_{\ell i} (g_{\ell i} \circ V)$  for the transfer action of the  $\ell$ -th mixture, and let  $\mathcal{A}V$  be the exact-rational polynomial computed symbolically from the presentation: killing multiplies, drift pairs the formal gradient, diffusion traces the formal Hessian against the derived covariance, each jump leg contributes  $\lambda_\ell (T_{\mu_\ell}V - V)$ . Show that evaluating  $\mathcal{A}V$  anywhere on  $\mathbb{R}^n$  equals the semantic integro-differential generator

$$-cV + \nabla V \cdot f + \frac{1}{2} \sum_{ij} a_{ij} \partial_{ij} V + \sum_{\ell} \lambda_{\ell} (T_{\mu_{\ell}}V - V)$$

of the evaluated profile, with the observable’s derivative data instantiated at the formal derivatives — for *every* presentation, with no conservativity or leg-shape hypothesis — and that at one Dirac leg with zero killing the semantic generator is the SDE frame’s operator (section 12.7) on the nose.

*Sketch.* Evaluation is an algebra homomorphism, so each field family passes through separately; the transfer of a finite mixture is a finite sum, exact at the polynomial stratum, and a list induction carries the leg sum. A sub-stochastic mixture adds no new semantics: its jump increment decomposes as Dirac-leg increments minus the mass deficit spent as killing — the standard convention for jump kernels of total mass below one [60]. The one-Dirac-leg tie is a computation collapsing the leg sum.

The identity of operators carries the verdict route with it: the martingale problem consumes its generator opaquely — the compensator argument never inspects the drift, diffusion, killing, or jump structure — so the SDE section’s solution concept, its derived continuous-time supermartingale, and its verdict headlines transplant verbatim to the multi-leg generator. Because this section’s splice holds with no side conditions,

the transplanted headlines hold for *every* presentation — killing, finitely many legs, sub-stochastic mixtures — with no conservativity or leg-shape hypothesis, where the SDE section’s headlines carried both. The single-Dirac-leg square then *factors* through the multi-leg one: profiles embed, the operators agree on the nose, and solutions transport along the identity, verdicts included. The boundaries that remain are the SDE square’s own: verdicts on the sampled grid, well-posedness not claimed, transport one-directional. All of it is mechanized, sorry-free, in the toolkit’s Lean tree (`lean/qlAux/`, modules `QtslAux.JumpDiffusion` and `QtslAux.JumpDiffusionMartingaleProblem`): the profile is `JdProfile`, the hypothesis-free splice is `genPoly_eval_eq_generator`, the degeneracy ties are `generator_one_dirac` and `toJd_generator_one_dirac`, the mixture-to-killing decomposition is `transferSum_sub_self`, and a two-leg control with every field family live pins the closed form (`two_leg_control`); on the verdict side, the solution concept is `MpSolution` at the multi-leg generator, the derived supermartingale is `supermartingale_of_gen_nonpos`, the sampled Dynkin class is `JdDynkinVil`, the headlines are `mp_avoid_row_of_genPoly` and `mp_avoid_init_of_genPoly`, the factoring is `generator_toJd` with `MpSolution.toJd`, and the end-to-end control’s presentation carries live rates on two legs with a genuine mixture (`mp_control`).

**Status.** Certification: two hand-derived systems check through the unmodified stack — a Brownian-perturbed risk process of the classical ruin-theory shape (drift helps, diffusion and claim jumps hurt; certified ruin bound 49/121 from its stated start), and a load-shedding system in which the state-dependent jump term *alone* carries the certificate against both unstable drift and diffusion. At  $n = 2$  the encounter composite carries all three families with full-rank correlated noise. Representation and production: the toolkit’s producer surface constructs presentations at the frame’s full profile generality — killing rows and multi-leg sub-stochastic mixture kernels included — in both languages, and derives the generator polynomial together with its per-leg rate rows symbolically from the presentation (the exact computation whose identity with the semantic generator is the Adequacy paragraph’s mechanized splice; derived and never trusted — the checker re-derives both). The API block below quotes receipted constructions, and the reference presentation exercising every field family at once — a Dirac leg beside a genuinely sub-stochastic mixture leg, with killing — is a committed cross-language byte-identity vector. Open: certification exercise of multi-leg jump kernels and state-dependent  $\sigma$  (fully representable and derivable as above, but no shipped certificate exercises them yet); time-bounded and discounted variants; closure.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ ,  $\text{pop}$ , and profile conformance are defined in section 12.1.

$$\frac{\begin{array}{c} \vec{x} \text{ declared state variables} \quad D \text{ drift rows} \quad N \text{ a noise presentation (section 12.7)} \\ J : \langle \text{mode?}, \text{rate}, \text{reset} \mid \text{mixture}, \text{reset\_image?} \rangle \text{ jump rows} \quad K \text{ killing rows (optional)} \end{array}}{\text{JumpDiffusion}(\vec{x}; D; N; J; K) : \text{System}} \quad \text{S-JUMPDIFF}$$

Jump rows carry rate a polynomial intensity and exactly one kernel form: reset a polynomial substitution, or mixture a finite weighted list of polynomial substitutions (sub-stochastic totals lawful — the deficit is killing); reset image an exact box. Killing rows carry a polynomial rate; an absent family is the conservative declaration.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s

shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## 12.11 Discrete-Time Markov Chains

**The frame.** Finite-state stochastic transition systems; the bread-and-butter question is certified reachability, with reward and hitting-time bounds beside it. A two-state weather chain makes the section's objects concrete: sunny stays sunny with probability  $\frac{3}{4}$ , rain persists with probability  $\frac{1}{2}$ , and a sunny start yields the two-step record (sunny, sunny, rain) with probability  $\frac{3}{4} \cdot \frac{1}{4} = \frac{3}{16}$  — one stored row spent per step, which is the whole compilation story below in miniature.

**Profile.** Outcome rows (*src*, *dst*, *reward*, *prob*) in exact rational arithmetic, rows summing to one per source, plus initial-distribution rows. Carrier: the declared finite state space. Time: counter.

**Counter time and the tick.** Composition into real time passes through the tick declaration of section 12.2 — part of the model type, not a checker convention, with the price of a jitter bracket over an exact tick certified rather than assumed (the factor-2.66 pair quoted there).

**Semantics.** The finite-state path measure, exact; backward-induction table soundness carried in checker-adjacent prose with its mechanized statement named. In the universe’s terms: the precise face (Remark 9.22) over discrete records, glued by the kernel-presented route of section 9.5, on which the natural extension reproduces local data exactly.

**Adequacy.** The compilation above is not merely well-typed; it is *adequate*: compiling and then denoting in the semantic universe agrees with interpreting classically and then including the classical object into the universe’s precise face. Stated self-contained, at the working scale of an exam problem:

**Problem 12.8** (adequacy of the chain compilation). Let  $S$  be a finite set,  $P \in \mathbb{Q}^{S \times S}$  a row-stochastic matrix,  $\iota \in \mathbb{Q}^S$  a distribution, and fix a horizon  $k$ . On the record space  $\Omega = S^{\{0, \dots, k\}}$  write  $\mu_{P, \iota}$  for the horizon- $k$  finite-dimensional distribution of the chain,

$$\mu_{P, \iota}(\omega) = \iota(\omega_0) \prod_{t < k} P(\omega_t, \omega_{t+1}),$$

the product form of Kemeny–Snell [135] and the horizon- $k$  generator of the cylinder-set path measure of Baier–Katoen [14]. Say a subprobability mass function  $\mu$  on  $\Omega$  *satisfies the compiled rows* when (i) for every  $\omega$ , the mass of  $\{\omega' : \omega'_0 = \omega_0\}$  equals the stored initial row  $\iota(\omega_0)$ , an absent row read as 0; and (ii) for every  $t < k$  and every  $\omega$ , writing  $C_t(\omega)$  for the event that a record agrees with  $\omega$  at all times  $\leq t$ , refinement by one step spends exactly one outcome row:  $\mu(C_{t+1}(\omega)) = \mu(C_t(\omega)) \cdot P(\omega_t, \omega_{t+1})$ , an absent row again read as 0. Show that  $\mu$  satisfies the compiled rows if and only if  $\mu = \mu_{P, \iota}$  — in particular the constraints force total mass one, so the ambient subprobability slack is never taken up.

*Sketch.* ( $\Leftarrow$ ) Downward induction from  $t = k$  gives the closed form  $\mu_{P, \iota}(C_t(\omega)) = \iota(\omega_0) \prod_{i < t} P(\omega_i, \omega_{i+1})$ : partition  $C_t(\omega)$  by the value at time  $t + 1$  and spend one row sum  $\sum_s P(\omega_t, s) = 1$  per step; both constraint families read off the closed form. ( $\Rightarrow$ ) Upward induction on  $t$  pins  $\mu(C_t(\omega))$  to the same prefix products; at  $t = k$  the prefix events are the atoms  $\{\omega\}$ , so all weights agree, and summing the atoms puts the total mass at one.

In the universe’s terms: the two constraint families, read as a formal conjunction, are the compiled system’s denotation at the per-element stratum of the credal stack, and the theorem says this loose arrow is isomorphic — by an invertible globular cell of the thin double category of per-element constraints — to the singleton inclusion of  $\mu_{P, \iota}$ : the precise face of Remark 9.22, whose ray form agrees with the singleton on the radially maximal slice that the verdict operators read. The statement and both directions are mechanized, sorry-free, in the toolkit’s Lean tree (Lean/su-functor/, module SuFunctor.Adequacy.Dtmc): the pointwise equivalence is `satAtoms_iff`, the invertible cell is `dtmc_adequacy`, and the mass identity is `pathLaw_mass`. The same module ties the exact-rational law to the standard monadic construction of the chain law in the mechanized probability library — iterated `PMF.bind` against the kernel — as `trajPMF_eq`, so the classical side of the square is the community’s mechanized object rather than a private restatement; the inclusion vocabulary shared by the sibling frames of this catalogue lives beside it (SuFunctor.Adequacy.Inclusions). The infinite-horizon path measure is deliberately a separate stratum: the laws above are its finite-dimensional distributions, and the  $\sigma$ -additive extension (Ionescu–Tulcea) belongs to the measure-theoretic tier.

**Status.** Certification is the most heavily exercised leg in the toolkit: the published-table campaign of section 2.3 (all seventeen rows of a peer-reviewed neural-certificate table [4] reproduced or refuted with exact arithmetic) and the tabular-tier campaign of section 2.4 (dozens of hitting and reward certificates) are both, at bottom, this frame’s machinery. Representation and production: the toolkit’s producer surface constructs the row grain in both languages and derives the one-step transfer and the generator values exactly from the stored rows — the compiled face of the Adequacy paragraph’s square and its generator kernel. Admission is the row grain’s own well-formedness: every source fibre totals exactly one — stochasticity is *declared by* the stored rows here, where the continuous-time sibling *derives* it from unconstrained rates, the same checker posture with the opposite direction of creation — so a sub-stochastic fibre refuses with its total (a deficit would be killing, which is the jump-diffusion frame’s vocabulary, never the chain’s).

The discrete segment-Dynkin identity is exercised in the test suite as an exact differential over a spread initial distribution, and the chain-3 mechanism is a committed cross-language byte-identity vector whose closed-form control includes the absorbing self-loop's computed zero (an absorbing state is its explicit self-loop row, the compiled grain's own representation — no flag). Open — and stated in full, since it is the list's recurring lesson: the frame has been exercised *beside* the modelling language, through producer pipelines, faster than it has been represented *in* it; native outcome rows through the ingestion path are the gap. The temporal-logic closure beyond reach and reach-avoidance (nested operators in the style of PCTL\*) is designed, and its first two strata are already in the language: state-level nesting is the tower discipline of the probability former — certificate-mediated: a child certificate's sublevel set enters as a parent claim's ordinary atom, cited through the judgment stratum (section 14.6.1) — and path-level recurrence shapes are definitional Streett instances (section 14.5.5). The genuine surplus — temporal operators nested with no intervening threshold — compiles by deterministic-monitor product: a finite deterministic monitor composed with the chain, acceptance read as Streett acceptance on the product, satisfaction transported back along the projection, with the quantitative case a reach stratum into the almost-sure accepting core. The next-step operator and the unbounded-until fence (section 14.9.4) are the named gaps; a certified depth-two artefact is the open exercise.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (`crates/mtk-catalogue/src/system/`), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{O : \langle \overline{src}, \overline{dst}, \overline{prob}, \overline{reward?} \rangle \text{ outcome rows in exact } \mathbb{Q}, \text{ unkeyed} \quad \iota? : \langle \overline{state}, \overline{prob} \rangle \text{ initial-distribution rows} \quad \tau? : \text{TickDecl}}{\text{DTMC}(O) : \text{System}} \quad \text{S-DTMC}$$

Unkeyed means no action anywhere ( $o.\text{action} = \perp$ , row by row) — the discipline that separates this former from the decision former sharing its rows.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.dtmc`

signature — `ts/src/system.ts`

```
/** S-DTMC: unkeyed outcome rows (+ init distribution, tick). */
export const dtmc = profileFactory("dtmc");

/** The derived DTMC generator kit: the one-step transfer
 * (P V)(s) =  $\sum_d p(s,d) \cdot V(d)$  and the generator values
 *  $\mathcal{N}V(s) = (P V)(s) - V(s)$  — the mechanized transferRow/genRow
 * contractions, whose recomputed rows are theorem-grade drift
 * premises. Derived, never trusted — the checker re-derives both. */
export interface DtmcGenKit {
  readonly gen: readonly StateVal[];
  readonly transfer: readonly StateVal[];
}
```

```

/** Derive the DTMC generator kit from a mechanism declaration and a
 * per-state certificate observable. Admission mirrors the WF
 * hypotheses under which the rows denote a chain: every roster
 * state's outcome fibre totals one (a sub-stochastic fibre refuses
 * with its total – deficit-as-killing belongs to the jump-diffusion
 * former), an action-keyed row refuses (the discipline separating
 * this former from the decision former sharing its rows), a stored
 * zero refuses (absence is the representation). Witness-shaped
 * refusals, never exceptions. */
export function dtmcGenKit(
  init: MechanismInit,
  cert: readonly StateVal[],
): Result<DtmcGenKit, Refusal> {
  const raw = native.sysDtmcGenKit(mechanism(init).nativeHandle, cert) as
    | { kit: DtmcGenKit }
    | { refusal: unknown };
  return "refusal" in raw
    ? refused(narrowRefusal<Refusal>(raw.refusal))
    : ok(raw.kit);
}

```

construction — ts/tests/system-native.test.ts

```

return sys.unwrap(
  sys.dtmc({
    name: "chain-3",
    outcomes: [
      { src: 0, dst: 0, prob: "1/3", reward: "0" },
      { src: 0, dst: 1, prob: "2/3", reward: "1" },
      { src: 1, dst: 2, prob: "1", reward: "5" },
      { src: 2, dst: 2, prob: "1" },
    ],
    initDist: [{ state: 0, prob: "1" }],
    tick: { kind: "exact", period: "1/50" },
  }),
);

```

The quoted construction is the committed cross-language byte-identity vector's own (the chain-3 mechanism), and the generator kit's closed-form control — transfer and generator on that same presentation, the absorbing self-loop's computed zero included — rides the test suite beside it. The kit's Rust face is `mtk_catalogue::system::dtmc_gen_kit`.

## 12.12 Continuous-Time Markov Chains

**The frame.** Exponential races over a finite state space; certified questions are time-bounded and unbounded reachability. A two-state repair chain is the toy to hold: a machine fails at rate  $\lambda$  and is repaired at rate  $\mu$ , so its jump chain alternates deterministically between up and down while the rates set only the clocks — the jump-chain/holding-time split at which the adequacy square below lives.

**Profile.** A shipped theory of its own: states, plus off-diagonal rate entries as a partial function — zero entries absent by construction, diagonal determined, so malformed rate matrices are unrepresentable rather than linted — plus generator-certificate rows. Time: continuous.

**Semantics.** The finite-state generator; the path measure is unique (no explosion at finite state), and the Dynkin and Ville bridges are named obligations, unconditional in this setting but still deliberately outside the kernel. At finite state the classical path-measure construction discharges, for this frame, the continuous-time extension debt section 9.5 names in general.

**Adequacy (jump-chain face).** The compilation above is adequate at its *time-abstract* stratum: the embedded jump chain — which states the process visits, in which order — is exact rational data, and compiling the rate rows then denoting agrees with interpreting the jump chain classically and including into the universe's precise face. Stated self-contained, at the working scale of an exam problem:

**Problem 12.9** (the jump-chain square). Let  $S$  be a finite set,  $q(s, s') \in \mathbb{Q}_{\geq 0}$  a transition rate for each ordered pair of distinct states, and  $\iota \in \mathbb{Q}^S$  a distribution. Write  $q(s) = \sum_{s' \neq s} q(s, s')$  for the exit rates, and let  $\Pi$  be the jump matrix of Norris [190]: when  $q(s) \neq 0$ ,  $\Pi(s, s') = q(s, s')/q(s)$  for  $s' \neq s$  and  $\Pi(s, s) = 0$ ; when  $q(s) = 0$ , the absorbing convention  $\Pi(s, s) = 1$  and  $\Pi(s, s') = 0$  otherwise. Fix a jump horizon  $k$  and write  $\mu_{q, \iota}$  for the horizon- $k$  path law of the chain  $(\Pi, \iota)$  on  $\Omega = S^{\{0, \dots, k\}}$  — the record of the first  $k$  jumps, not of clock time. The compiled presentation stores the off-diagonal rate rows  $(s, s') \mapsto q(s, s')$ , an absent row read as 0 and a diagonal row unrepresentable; the jump closure is the *computed* row set  $\Pi$ , and a subprobability mass function  $\mu$  on  $\Omega$  satisfies the closure exactly when it satisfies the chain constraints of section 12.11 at the rows  $(\Pi, \iota)$ . Show: (i) the closed rows are row-stochastic, although the rate rows carry no row-sum constraint; (ii)  $\mu$  satisfies the closure's constraints if and only if  $\mu = \mu_{q, \iota}$  — in particular the constraints force total mass one; and (iii)  $\Pi(s, s') q(s) = q(s, s')$  for all  $s \neq s'$ , absorbing states included.

*Sketch.* (i) is one division: at a non-absorbing state the row sums to  $q(s)/q(s)$ , at an absorbing state to a point mass — the stochasticity of the jump chain is derived, never assumed. The pair  $(\Pi, \iota)$  is then a finite chain, and both directions of (ii) are the chain problem verbatim at these rows: the downward induction reads off the closed form on prefix events, the upward induction pins any satisfying  $\mu$ , and mass one follows by summing the atoms. (iii) is the recovery direction of the jump-chain/holding-times decomposition: at

an absorbing state both sides vanish, since nonnegative rates summing to zero vanish individually. No further stochastic content is specific to the continuous-time former — closing the rate rows before or after compilation stores the same rows, which is the whole remaining obligation.

In the universe’s terms: the jump closure denotes as a loose-arrow diagram at the per-element stratum, and the theorem exhibits an invertible globular cell to the singleton inclusion of the jump-chain law — the chain square instantiated at the jump chain. The statement and both directions are mechanized, sorry-free, in the toolkit’s Lean tree (`lean/su-functor/`, module `SuFunctor.Adequacy.CtmcJumpChain`): the invertible cell is `ctmc_jump_adequacy`; the compile-commutes triangle — definitional, and the one obligation well-formedness alone could not carry, since any rate table closes to *some* stochastic rows — is `compile_jump_comm`; the derived stochasticity is `jumpRows_wf`; the rate factorization is `jumpChain_step_mul_exit`; and the profile’s diagonal-determined convention is carried as theorems rather than prose (`compileCtmc_diag_blind`, `jumpLaw_diag_blind`: the compiled key type cannot express a diagonal read). The chain connector transports unchanged (`jumpTrajPMF_eq`), which is the exact extent of the community tie: the mechanized probability library has no continuous-time Markov machinery, so the jump chain is tied as the discrete-time chain it is. Deliberately separate strata: the *time-law* stratum — exponential holding times with parameter  $q(s)$ , whose transients are irrational and hence outside this exact-rational grain — carries the rest of the continuous-time path semantics named in the Semantics paragraph above; *uniformization* is a different discrete reduction (self-loops against a common rate) and not this one; Markov automata under a declared scheduler consume this square together with the decision-former machinery (section 12.15); the infinite-horizon extension is separate exactly as for chains.

**Status.** Certification: three certified bounds over four kernel-checked fixtures — time-bounded reach for an explicit repair chain ( $P(\text{down by } T) \leq T/200$ , with the equalized certificate’s constant meeting the expected hitting time exactly, no matrix exponential anywhere), a catastrophe-entry bound exercising arbitrary rate matrices, and an unbounded-reach bound for a nine-state epidemic chain (a Ville argument spending two fixtures: the generator sequent and its nonnegativity side condition), against an exact ground-truth ruin probability of 35/274391. Representation and production: theory and instance rows are in place and compile through the reference lane, and the toolkit’s producer surface constructs the rate grain in both languages and derives the generator values, the exit rates, and the jump-closure rows exactly from the stored entries — the compiled face of the Adequacy paragraph’s square: the closure’s row-stochasticity, a theorem there, is re-run as arithmetic here, the rate factorization is exercised in the test suite as an exact differential, and the machine-repair chain is a committed cross-language byte-identity vector whose closed-form control is its own certified values ( $AV = 3/755$  at every non-bad state, the equalized certificate’s constant, derived and never trusted). Open: nested temporal operators; the ingestion gap; closure.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ ,  $\text{pop}$ , and profile conformance are defined in section 12.1.

$$\frac{R : \overrightarrow{\langle \text{src}, \text{dst}, \text{rate} \rangle} \text{ off-diagonal rate entries } (\text{src} \neq \text{dst}) \quad \iota? \text{ initial-distribution rows}}{\text{CTMC}(R) : \text{System}} \text{ S-CTMC}$$

Rate entries are an off-diagonal partial function: zero entries are absent by construction and the diagonal is determined, so a malformed rate matrix is unrepresentable rather than linted.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a

native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## TypeScript `system.ctmc`

signature — `ts/src/system.ts`

```
/** S-CTMC: off-diagonal rate entries as a partial function. */
export const ctmc = profileFactory("ctmc");

/** One per-state exact-rational value: the discrete-former
 * certificate observable's grain (and the kit outputs' row shape). */
export interface StateVal {
  readonly state: number;
  readonly val: string;
}

/** The derived CTMC generator kit: the generator values
 *  $\dot{V}(s) = \sum_d q(s,d) \cdot (V(d) - V(s))$ , the exit rates, and the
 * jump-closure rows (Norris's convention: proportional split at a
 * non-absorbing state, the self-loop point mass at an absorbing
 * one) — row-stochastic by derivation, never by declaration.
 * Derived, never trusted — the checker re-derives all three. */
export interface CtmcGenKit {
  readonly gen: readonly StateVal[];
  readonly exitRates: readonly StateVal[];
  readonly jumpRows: readonly {
    readonly src: number;
    readonly dst: number;
    readonly prob: string;
  }[];
}

/** Derive the CTMC generator kit from a mechanism declaration and a
 * per-state certificate observable. The mechanized contract is the
 * CTMC adequacy square's, jump-chain face: the closure's
 * row-stochasticity is a theorem there (derived stochasticity), and
 * the rate factorization  $\Pi(s,d) \cdot q(s) = q(s,d)$  ties the outputs. The
 * grain fences (diagonal, parallel, or nonpositive rate entries;
 * missing or duplicate certificate values) come back as
 * witness-shaped refusals, never exceptions. */
export function ctmcGenKit(
  init: MechanismInit,
  cert: readonly StateVal[],
): Result<CtmcGenKit, Refusal> {
  const raw = native.sysCtmcGenKit(mechanism(init).nativeHandle, cert) as
    | { kit: CtmcGenKit }
    | { refusal: unknown };
  return "refusal" in raw
    ? refused(narrowRefusal<Refusal>(raw.refusal))
    : ok(raw.kit);
}
```

construction — `ts/tests/system-native.test.ts`

```
// CTMC diagonal rate entry: index and state.
const diag = sys.ctmc({
  rates: [
    { src: 0, dst: 1, rate: "1" },
    { src: 1, dst: 1, rate: "2" },
  ],
});
assert.ok(!diag.ok);
```

The TS corpus exercises this factory through its refusal geometry (the corpus's discipline that failure geometry is routing advice); the quoted construction is that witness, and the happy-path byte authority is the Rust corpus opposite — the machine-repair mechanism is a committed cross-language byte-identity vector, and the generator kit's closed-form control is its own certified values. The kit's

Rust face is `mtk_catalogue::system::ctmc_gen_kit`.

**Rust** `mtk_catalogue::system::presets::Ctmc::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```

    preset!(
        /// System Catalogue: CTMC profile – off-diagonal rate entries as
        /// a partial function (zero entries absent; diagonal determined,
        /// never stored).
        Ctmc, "CTMC",
        req = [Rates],
        allowed = [InitDist],
        extra = no_diagonal_rates
    );

```

construction — `crates/mtk-catalogue/tests/builders.rs`

```

    let ctmc = MechanismBuilder::new().rate(0, 1, r(3, 2)).finish();
    Ctmc::manifest(ctmc).unwrap();

```

## 12.13 Markov Decision Processes

**The frame.** Kernels keyed by action; the frame’s whole point is quantification over policies. The toy to hold: a machine that can be repaired now (a certain cost) or run on (a risk of failure) — two actions at every state, and the question that makes the frame is a guarantee holding whichever way the operator chooses, forever.

**Profile.** Outcome rows keyed by action; a policy is a separate mechanism, composed in — the closed loop is a composite, not a monolith. Time: counter.

**Semantics.** Per-policy path semantics as for chains; the quantification over policies lives in the credal (imprecise-measure) layer of the System semantics (Definition 9.15), where a specification reads the denotation at a stated degree of pessimism.

**Adequacy (fixed-policy face).** The closed-loop composite is adequate in the same sense as the chain compilation of section 12.11 — compiling both mechanisms, closing the loop at the row level, and denoting agrees with interpreting classically and including into the universe’s precise face — and the proof is the chain square, reused wholesale. Stated self-contained, at the working scale of an exam problem:

**Problem 12.10** (the fixed-policy square). Let  $S$  and  $A$  be finite sets,  $p \in \mathbb{Q}^{S \times A \times S}$  a family of kernels with  $\sum_{s'} p(s' | s, a) = 1$  for every state–action pair,  $\iota \in \mathbb{Q}^S$  a distribution, and  $\pi$  a memoryless randomized policy: at each state, a distribution over actions — the stationary randomized Markov class of Puterman [203], a deterministic policy being the unit-mass special case. Fix a horizon  $k$  and write, on  $\Omega = S^{\{0, \dots, k\}}$ ,

$$\mu_{p, \iota, \pi}(\omega) = \iota(\omega_0) \prod_{t < k} \sum_a \pi(a | \omega_t) p(\omega_{t+1} | \omega_t, a),$$

the fixed-policy trajectory law. The compiled presentation keeps the two mechanisms separate: action-keyed outcome rows  $(s, a, s') \mapsto p(s' | s, a)$  and policy rows  $(s, a) \mapsto \pi(a | s)$ , an absent row in either read as 0; the closed loop is the *computed* row set  $P_\pi(s, s') = \sum_a \pi(a | s) p(s' | s, a)$ , and a subprobability mass function on  $\Omega$  satisfies the composite exactly when it satisfies the chain constraints of section 12.11 at the rows  $(P_\pi, \iota)$ . Show that  $\mu$  satisfies the composite’s constraints if and only if  $\mu = \mu_{p, \iota, \pi}$  — in particular the constraints force total mass one.

*Sketch.* One exchange of finite sums shows the mixed matrix  $P_\pi$  is row-stochastic —  $\sum_{s'} P_\pi(s, s') = \sum_a \pi(a | s) \sum_{s'} p(s' | s, a) = 1$  — spending each policy row’s total exactly once against the per-action row sums. The pair  $(P_\pi, \iota)$  is therefore a finite chain, and  $\mu_{p, \iota, \pi}$  is by construction its product-form path law. Both directions are then the chain problem verbatim at these rows: the downward induction reads off the closed form on prefix events, the upward induction pins any satisfying  $\mu$ , and mass one follows by

summing the atoms. No further stochastic content is specific to the decision former — closing the loop before or after compilation stores the same rows, which is the whole remaining obligation.

In the universe’s terms: the composite denotes as a loose-arrow diagram at the per-element stratum, and the theorem exhibits an invertible globular cell to the singleton inclusion of the fixed-policy law — the same form as the chain square, because it *is* the chain square instantiated at the closed loop. The statement and both directions are mechanized, sorry-free, in the toolkit’s Lean tree (lean/su-functor/, module SuFunctor.Adequacy.Mdp): the invertible cell is `mdp_adequacy`, the compile-commutes triangle — definitional, and the one obligation well-formedness alone could not carry, since any single action’s rows are also row-stochastic — is `compile_close_comm`, and the mass identity is `pathLaw_mass`. The module also ties policy selection to the mechanized probability library’s own vocabulary: the closed-loop kernel is the monadic composition of the policy’s action distribution with the action-indexed kernel (`closedLoop_stepPMF`, one `PMF.bind`), and the trajectory-law connector of the chain section transports unchanged (`trajPMF_eq`). Deliberately separate strata: the *open-policy* face — the claim uniform over all policies, whose inclusion lands a *set* of laws in the credal layer rather than a singleton — is the imprecise reading of the Semantics paragraph above and is not this square (it is the next); *time-dependent* policies close to a time-inhomogeneous chain, outside the stationary grain stated here; Markov automata under a declared scheduler share this square’s mixing machinery but carry exponential holding times, so their square is *continuous-time* material (section 12.15); the infinite-horizon extension is separate exactly as for chains.

**Adequacy (demonic face).** The open-policy face is the first *genuinely imprecise* adequacy statement: what compilation must preserve is no longer a single law but the *set* of laws the decision process can exhibit, and the square says the compiled, policy-free presentation determines that set exactly. Stated self-contained, at exam scale:

**Problem 12.11** (the demonic square). Data as in the fixed-policy problem above — finite  $S$  and  $A$ , action-keyed kernels  $p$ , initial distribution  $\iota$  — but with *no* policy declared. The demonic semantics of the decision process at horizon  $k$  is the set of its closed-loop trajectory laws,

$$D = \{ \mu_{p,\iota,\pi} : \pi \text{ a memoryless randomized policy} \},$$

the adversary ranging over the stationary randomized class of Puterman [203] — the scheduler-quantified semantics of probabilistic model checking [14], and demonic choice in the sense of McIver and Morgan [176]. On the compiled side, call a subprobability mass function  $\mu$  on  $\Omega$  *admitted* by the action-keyed rows when *some* well-formed policy-row set closes the loop onto chain constraints that  $\mu$  satisfies — the rows carry no policy family; the demon’s choice is the separate mechanism, existentially quantified. Show: (i)  $\mu$  is admitted if and only if  $\mu \in D$ ; (ii) every member of  $D$  has total mass one, and consequently the downward-closed credal set generated by  $D$  — the union of the segments  $[0, 1] \cdot \mu$  over  $\mu \in D$  — has exactly  $D$  as its set of radially maximal elements; (iii) for an event  $E$  and threshold  $q$ , the credal set’s lower verdict for  $P(E) \geq q$ , and its upper verdict for the downward-closed constraint  $P(E) \leq q$ , each hold if and only if the corresponding bound holds under *every* policy.

*Sketch.* Claim (i) is the fixed-policy problem, quantified: a witnessing scheduler’s rows assemble a memoryless policy whose closed loop the chain constraints pin, and conversely every policy compiles to a witnessing scheduler — no new stochastic content. In (ii), mass one is the chain mass identity at each closed loop; for the slice, a strictly interior point of a segment escapes upward to its own base, while an upward scaling of one member landing on *another* member’s segment would have to scale mass past the common value — equal mass is exactly what forbids cross-member domination, and it is not decorative: in the unequal-mass pair  $\{\mu, \frac{1}{2}\mu\}$  the half element is dominated across segments and drops out of the slice. In (iii), the lower verdict reads the radially maximal slice (Remark 9.16), which by (ii) is  $D$  itself; the upper verdict reads the whole set, and downward closure of  $P(E) \leq q$  makes it blind to the segments’ interiors. Reading a lower bound against the whole set instead would refuse every positive threshold — the zero measure lies in every segment — which is the slice discipline’s whole content, surviving the passage to sets.

In the universe’s terms: the demonic reading of the compiled former and the union-of-singletons inclusion of  $D$  are isomorphic by an invertible globular cell at the per-element stratum — the first adequacy square whose bottom edge is set-valued, one singleton inclusion per policy (`unionSingletons`) — and the credal presentation, the union of the members’ rays (`FinMDP.demonicCredal`), reconciles with  $D$  through the

radially maximal slice, which is what the verdict operators read. The presentation is radial, and in general *not* convex: a mixture of two deterministic-policy path laws is realized by no memoryless policy, only by an ex-ante correlated scheduler, so the closed convex hull is the coarser convex reading — and the slice reconciliation is a statement the hull would coarsen. The mechanized results consume radially and equal mass only; closedness of the policy-to-law image, which would make the union a credal body outright, is not among them. The statement and both directions are mechanized, sorry-free, in the toolkit’s Lean tree (`lean/su-functor/`, modules `SuFunctor.Adequacy.EnvelopeUnion` and `SuFunctor.Adequacy.MdpDemonic`): the invertible cell is `mdp_demonic_adequacy`, with admission predicate `demonicC` and feeding lemma `demonicC_iff`; the equal-mass slice reconciliation is `maxSlice_unionRays`, its family-bound direction hypothesis-free (`maxSlice_unionRays_subset`), instantiated at mass one by `demonic_maxSlice`; the uniform-over-policies verdict theorems are `satCredal_lower_demonicCredal` and `satCredal_upper_demonicCredal`; and the degeneracies are mechanized rather than smoothed: the whole-set reading of a lower bound refuses every positive threshold (`not_satCredal_upper_demonicCredal_gec`); an action-free process is well-formed yet admits no policy at all (`isEmpty_policy_iff`), so both verdict kinds pass vacuously (the  $\forall$ -over-no-adversaries convention, the empty-policy union staying below bottom with no body); and the unequal-mass pair witnesses the slice lemma’s hypothesis (`not_maxSlice_unionRays_halfPair`). Deliberately separate strata, unchanged from the fixed-policy face: memoryless policies only; the *angelic* reading — existential over policies — is a different operator from the universally quantified verdict pair and is not built here; the infinite-horizon extension is separate exactly as for chains.

**Status.** An asymmetric grade, stated as such. *Fixed policy*: shipped — the controller-checkpoint certificates of the experiments chapters are policy-composed MDP verification, and the exact value-iteration route [112, 204] exports value functions as certificate input. The toolkit’s producer surface now constructs the closed loop itself in both languages: the policy arrives as the scheduler grain — the compiled face of the composed policy mechanism, never a family of the decision former, exactly the factoring the formation rule below states — and the kit derives the closed chain (self-loops kept, initial rows verbatim) and its generator by handing the closure to the chain kit, the square’s engine reuse run producer-side. The mixing exchange — the compile-commutes triangle — is re-derived as an exact differential in the test suite through a read that never touches the closure, with the deterministic read-through as its control; policy support discipline is the automaton’s (support within the enabled pairs, mass one at every state, and a state with no enabled actions refuses — nothing sound closes there, the empty-action degeneracy’s producer face); and the patrol mechanism is a committed cross-language byte-identity vector. *Uniform over policies*: the open-nondeterminism question is designed at the semantics layer and exercised by workshop fixtures with checker acceptance — not yet by a published reproduction target. Until that leg ships as a reproduction target, this frame is graded on its closed-loop half alone — which is precisely the half that does not distinguish it from section 12.11. Open: the quantified leg end to end; the ingestion gap; closure.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{O : \langle \text{src, action, dst, prob, reward?} \rangle \text{ outcome rows, every row action-keyed} \quad \iota? \text{ initial-distribution rows} \quad \tau? : \text{TickDecl}}{\text{MDP}(O) : \text{System}} \quad \text{S-MDP}$$

The same outcome rows as the chain former, all action-keyed; the policy is deliberately *not* a premise — it is a separate mechanism, composed in, so the closed loop is a composite.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## TypeScript `system.mdp`

signature — `ts/src/system.ts`

        prob: r(1, 1),
        reward: None,
    })
    .finish();
Mdp::manifest(mdp).unwrap();

```

## 12.14 Partially Observable Markov Decision Processes

**The frame.** Kernels keyed by action, as for the decision former — plus an observation channel, and the frame’s whole point is that the policy sees observations, not states. The classical formulation is Åström’s [10]: optimal control of a Markov process with incomplete state information. The toy to hold is the classic two-door problem — the *tiger* problem of the planning literature [129]: a prize behind one of two doors, a hazard behind the other, and a listening action whose report is right only most of the time. The question that makes the frame is a guarantee on achieved value for a controller that can never look behind the doors — only accumulate evidence about them.

**Profile: none — a composition pattern.** This frame adds no formation rule, no new mechanism family, and no new semantic species; it stands to the decision former of section 12.13 as the delay equation of section 12.6 stands to the ODE cell — a composite of inventory the catalogue already carries, presented through a wiring. The pieces: the *environment* is a decision-former mechanism, action-keyed outcome rows over a state the composite will hide; the *observation channel* is an ordinary mechanism whose rows carry kernels from state to observation symbols (an action-dependent channel folds in by state augmentation); the *controller* is a separate mechanism whose inputs are the channel’s outputs, never the environment’s state; and the loop closes through a *delayed trace* — the feedback row of the composition-patterns chapter’s delay inventory (section 13.10.5), which names this very loop as its flagship construction, and whose one-step degenerate case, the tick register, is the medium a counter-time closed loop needs. Where the delay-equation composite ran its feedback through a continuous transport medium, this one runs it through the tick register: the same pattern family, at the counter-time profile.

The wiring is not packaging; it is the frame’s semantic content. What distinguishes a partially observable decision process from the decision former is *which wires reach the policy*, and the composite carries that distinction as typing: the controller’s inputs are, by the shape of the pattern, the observation channel’s outputs together with its own state, so there is no way to write an instance of the pattern whose policy reads hidden state. Partial observability is a composition pattern, not a new model class.

**Semantics.** Per-policy path semantics on the closed loop’s trajectory law, exactly as for the decision former, with the quantification over policies again living in the credal layer (Definition 9.15) — and the one genuinely new ingredient relative to section 12.13 is the class quantified over: *observation-measurable* policies, policies factoring through the history of observations and of their own past actions, never the history of states. Stated classically, the policy is adapted to the observation filtration; stated compositionally, the restriction is carried by the wiring itself, which is what the paragraph above bought — the measurable-selection bookkeeping that the frame’s textbook development devotes to this restriction attaches here to compile-level metatheory, part of the square owed below, not of the presentation. The belief-state reformulation enters the same way, as presentation rather than semantics: Åström’s re-reading of the loop as a fully observed decision process on the belief simplex [10] is, in this inventory, a particular choice of controller — a belief-tracking mechanism whose internal state is a distribution over environment states, updated observation by observation, composed in like any other policy. (In unnormalized coordinates the exact Bayes update is polynomial — linear in the belief and in each mechanism’s rows, with no division — hence ordinary mechanism content; the normalized update, a ratio, is not, which is why the unnormalized form is the one the inventory stages.) The simplex is controller state, not a new semantic carrier.

**Adequacy.** Owed, and stated as such: no square is mechanized for this frame yet. What the fixed-policy face must say is engine reuse once more — at a declared observation-measurable policy, the environment, channel, and controller compile to rows, the loop closes at the row level, and the composite is a chain on finitely many reachable states at any fixed horizon (one belief per action–observation history), so

the obligation has the shape the decision former discharged in section 12.13, with the controller's belief coordinate folded into the composite state. The quantified face inherits the demonic square's set-valued form, with the adversary now ranging over the observation-measurable class — policies reading strictly less than the state, though carrying memory the stationary class of section 12.13 deliberately excluded — and the delayed trace is what makes the restriction structural rather than side-conditional. The intended first certificate is a lower bound on achieved value for the two-door problem, living on the belief simplex: a finite family of affine functionals on the simplex — the  $\alpha$ -vector presentation of Smallwood and Sondik [221] — each dominated by its witness action's Bellman backup under the discounted criterion, certifying at once a value floor and the policy that achieves it.

**Status.** Design of record, with the certificate route already exercised. The wiring — environment, observation channel, belief-tracking controller, delayed trace — is the composition-patterns chapter's own flagship construction (section 13.10.5), the producer surface for the delayed trace is landed there, and the decision former's closed-loop producer machinery is the engine the fixed-policy face will reuse. The two-door lower bound has been produced and checked in the workshop by the route the adequacy paragraph names — an exact-rational  $\alpha$ -vector certificate with per-state Bellman-domination witnesses, re-verified by a small exact checker — not yet as a published reproduction target, so the frame is graded here on design and workshop evidence alone. Open: the fixed-policy square; the quantified face end to end; promotion of the two-door certificate to a reproduction target; and the ingestion gap, as everywhere.

No formation rule accompanies this section: that absence is the section's content, for the same reason as in section 12.6 — the frame *is* a wiring of formers the catalogue already carries, and a dedicated former would store as data what the composite derives by shape.

## 12.15 Markov Automata

**The frame.** Exponential races, probabilistic branching, and nondeterministic action under maximal progress — the frame that composes sections 12.12 and 12.13.

**Profile.** Assembled by composition, not by a new theory: the chain frame's rate idiom, the decision frame's action-kernel idiom aimed at immediate transitions, and exactly one new atom — a scheduler declaration — with a closure bridge delivering the closed object as an ordinary continuous-time chain, certificate and all. Maximal progress is stated as structure: timed rows at instantaneous states are unrepresentable.

**Semantics.** The interleaving semantics via a fixed-scheduler reduction note (closure formula, self-loop thinning, Zeno-freedom as the closure's checked assertion), with path-measure bridges inherited unchanged from the chain frame.

**Adequacy (fixed-scheduler face).** The closure bridge above is adequate at the automaton's *time-abstract* stratum: under a declared scheduler, closing the compiled rows to a chain and then reading its jump skeleton agrees with interpreting the automaton classically and including into the universe's precise face. Stated self-contained, at the working scale of an exam problem:

**Problem 12.12** (the fixed-scheduler square). Let  $S$  and  $J$  be finite sets (the Markovian and the instantaneous states of a closed Markov automaton in the sense of Eisentraut, Hermanns, and Zhang [67]),  $A$  a finite action set. The data are: rates  $q(s, x) \in \mathbb{Q}_{\geq 0}$  for  $s \in S$ ,  $x \in S \sqcup J$  with  $x \neq s$  — a timed row at an instantaneous state and a diagonal entry are both *unrepresentable*, which is the maximal-progress assumption and the determined diagonal stated as structure — immediate kernels  $b(j, a, \cdot)$ , each a distribution on  $S \sqcup J$ ; an initial distribution  $\iota$  on  $S \sqcup J$ ; a scheduler  $\varsigma$  assigning each  $j \in J$  a distribution over  $A$ ; and a rank  $\rho: J \rightarrow \mathbb{N}$  such that the mixed immediate kernel  $f(j, x) = \sum_a \varsigma(j)(a) b(j, a, x)$  satisfies  $\rho(j') < \rho(j)$  whenever  $f(j, \text{in}(j')) \neq 0$  — the Zeno-freedom assertion, carried as a ranking witness. Define the absorption kernel  $P$  by iterating  $f$  (fuel one past the largest rank), a point mass at each Markovian state, and the closed chain by  $q^\varsigma(s, s') = \sum_x q(s, x) P(x)(s')$  for  $s' \neq s$ , with initial distribution  $\iota$  pushed through  $P$ . Show: (i)  $P$  is a distribution over  $S$  from *every* state, although neither the rate rows nor the iteration carried a normalization constraint, and it is the *unique* solution of the absorbing-system equations; (ii) the closed exit rate is the original exit rate minus the mass  $P$  returns to the source (self-loop thinning), so a scheduler can only remove

activity; (iii) writing  $q(s)$  for the exit rates and  $\Pi$  for the jump matrix of the automaton's timed part on  $S \sqcup J$  (instantaneous states rate-absorbing), the closure also reads  $q^\epsilon(s, s') = q(s) \sum_x \Pi(\text{in}(s), x) P(x)(s')$  — the race-then-jump-then-absorb spelling agrees with the rate spelling; and (iv) a subprobability mass function  $\mu$  on the jump-horizon- $k$  records of  $S$  satisfies the jump closure of the scheduler closure of the compiled rows if and only if  $\mu$  is the closed chain's jump-chain path law.

*Sketch.* (i) is an induction along the rank: the mixed kernel is row-stochastic by the policy mixing exchange of section 12.13, and past the rank the iteration has stabilized — Zeno-freedom is spent exactly here, since an immediate self-loop would never absorb; uniqueness is the same induction applied to the difference of two solutions. (ii) is the mass computation of (i) summed against the rate rows. (iii) is the rate-factorization identity of section 12.12 —  $\Pi(s, x) q(s) = q(s, x)$ , absorbing states included — applied under the absorption sum. (iv) is the chain problem verbatim at the closed rows: the one genuinely automaton-shaped obligation is that scheduler-closing the compiled rows is the compilation of the classically closed chain, which holds definitionally when both routes read the same rows through the same guarded reads and the same absorbing iteration — and it is what pins the closure to the declared scheduler and the declared rates, since well-formedness alone can see neither.

In the universe's terms: the scheduler closure followed by the jump closure denotes as a loose-arrow diagram at the per-element stratum, and the theorem exhibits an invertible globular cell to the singleton inclusion of the closed jump law — the chain square instantiated twice, three storeys of engine reuse with no new induction. The statement and both directions are mechanized, sorry-free, in the toolkit's Lean tree (lean/su-functor/, module SuFunctor.Adequacy.MarkovAutomaton): the invertible cell is `ma_adequacy`; the rate-closure triangle — definitional — is `compile_closeMa_comm`; the acyclic-absorption package is `absorbIter_mass`, `absorbIter_unique`, and `absorbIter_stab`; the two closure spellings are `close_offRate_factor`, consuming the chain face's `jumpChain_step_mul_exit`; the thinning identity and its inequality are `close_exitRate_thinning` and `close_exitRate_le`; and the profile's structural conventions are carried as theorems (`compileMa_diag_blind`: the compiled key type can express neither a self-rate nor a timed row at an instantaneous state). The scheduler grain is the decision former's policy grain reused verbatim, and the community tie is the chain connector transported through both closures (`FinMA.trajPMF_eq`) — the mechanized probability library has no Markov-automaton machinery, and the connector says so rather than dressing the transport as more. Deliberately separate strata: the exponential *time-law* stratum, inherited from section 12.12; *scheduler quantification*, the envelope stratum, addressed by the demonic face in the next paragraph; *parallel composition and visible actions*, the open-automaton face (this square stages one closed component); history-dependent schedulers; and non-Zeno-free automata, outside the square by hypothesis rather than silently discharged.

**Adequacy (demonic face).** The scheduler-quantification face, and the set-valued square at continuous time — the automaton sibling of section 12.13's demonic face, with one genuinely automaton-shaped complication: each scheduler's closure consumes a Zeno-freedom certificate. Stated self-contained, at exam scale:

**Problem 12.13** (the demonic square, at continuous time). Data as in the fixed-scheduler problem above — finite  $S, J, A$ ; rates  $q$ ; immediate kernels  $b$ ; initial distribution  $\iota$  — but with *no* scheduler declared. Instead, a single rank  $\rho: J \rightarrow \mathbb{N}$  is given that strictly decreases along every immediate *branch* row:  $\rho(j') < \rho(j)$  whenever  $b(j, a, \text{in}(j')) \neq 0$ . (i) Show one rank serves every adversary: for each scheduler  $\varsigma$ , the mixed kernel  $f_\varsigma$  satisfies the fixed-scheduler problem's Zeno-freedom assertion with the same  $\rho$ , so the closed chain and its jump law  $\mu_\varsigma$  are defined for all  $\varsigma$  simultaneously. (ii) Show the object outranks its certificate: if  $\rho'$  is any other rank certifying some scheduler's mixed kernel, the closure at  $\rho'$  yields the same law — so the demonic semantics at horizon  $k$ ,

$$D = \{ \mu_\varsigma : \varsigma \text{ a memoryless randomized scheduler} \},$$

depends on the automaton and the horizon alone. (iii) On the compiled side, call  $\mu$  *admitted* when *some* well-formed scheduler-row set closes the compiled automaton rows, at the rank's working fuel, onto chain constraints that  $\mu$  satisfies; show  $\mu$  is admitted if and only if  $\mu \in D$ , and that every member of  $D$  has mass one, so the downward-closed credal set generated by  $D$  has exactly  $D$  as its radially maximal slice and the verdict pair reads as bounds uniform over *every* scheduler. (iv) Show the certificate forces somewhere to absorb into: if  $J$  and  $A$  are inhabited, a branch-certified automaton must have a Markovian state.

*Sketch.* (i) is support bookkeeping: a mixture's support lies in the union of the branch supports, so a rank uniform in the branches is uniform in the adversary — the quantifier commutes through the certificate. (ii) both certificates are spent at a common fuel past both ranks, where the absorbing iteration has stabilized twice over; since the two closures then agree on everything the jump law reads, the laws coincide. (iii) is the demonic decision problem of section 12.13 run through two closures: stored scheduler rows assemble a scheduler, the rate-closure and jump triangles collapse the pipeline to a compiled chain, and the chain constraints pin the law — four storeys of engine reuse, no new induction; the mass, slice, and verdict claims are the equal-mass reconciliation verbatim, the working fuel being exactly where the branch certificate is spent on the compiled side. (iv) the minimal-rank instantaneous state's branch row is a distribution, so it is supported somewhere, and every instantaneous destination would have to descend below the minimum.

In the universe's terms: the demonic reading of the compiled automaton rows and the union-of-singletons inclusion of  $D$  are isomorphic by an invertible globular cell at the per-element stratum, and the credal presentation reconciles with  $D$  through the radially maximal slice, exactly as at the decision former — the presentation radial, not convex, for the same reason. The statement and both directions are mechanized, sorry-free, in the toolkit's Lean tree (lean/su-functor/, module SuFunctor.Adequacy.MaDemonic): the invertible cell is `ma_demonic_adequacy`, with admission predicate `maDemonicC` and feeding lemma `maDemonicC_iff`; the one-rank-serves-every-adversary certificate is `FinMA.BranchZenoFree` with `zenoFree_of_branch`; the canonicity receipts are `FinMA.pathLaw_rank_irrel` and `FinMA.demonicLaws_rank_irrel`; the slice reconciliation is `ma_demonic_maxSlice`; the uniform-over-scheduler verdict theorems are `satCredal_lower_maDemonicCredal` and `satCredal_upper_maDemonicCredal`; and the degeneracies are mechanized rather than smoothed — the scheduler space has two nonemptiness routes (with no instantaneous states, the closed-chain boundary, `Policy.nonempty_of_isEmpty`; with them, schedulers vanish exactly when actions do, `Policy.isEmpty_iff`), the whole-set reading of a lower bound refuses every positive threshold (`not_satCredal_upper_maDemonicCredal_geC`), the empty scheduler space validates both verdict kinds vacuously, and the Markovian floor of task (iv) is `FinMA.nonempty_markovian`. The general object for automata where only *some* schedulers admit a rank — the union over Zeno-certified scheduler resolutions, each carrying its own rank (`FinMA.CertScheduler`, `FinMA.demonicLawsCert`) — is built at the classical level and collapses to  $D$  under a branch-level certificate (`FinMA.demonicLawsCert_iff`, spending rank-irrelevance); a compiled square for that partial-Zeno stratum would carry rank witnesses inside the admission predicate, and is deliberately separate. Also separate, unchanged from the fixed-scheduler face: the time-law stratum; history-dependent schedulers; parallel composition; the angelic (existential-over-scheduler) reading, a different operator from the universally quantified verdict pair.

**Status.** Certified at the fixed-scheduler grade, with the scheduler *declared as part of the claim*: a two-station polling automaton with an unreliable server — the classic Markov-automata polling benchmark [102], shrunk to capacity one — closed under a stated preference scheduler to a ten-state chain, carries  $P(\text{job lost by } T \mid \text{empty}) \leq T/5$  through the unmodified chain machinery. The mutant battery has teeth in the direction that matters: tampering with the declared scheduler makes the same certificate refuse with direct witnesses — the declaration does real work in the claim. Representation and production: the toolkit's producer surface constructs the composed profile in both languages and derives the entire closure bridge exactly from the stored rows — the sort partition, the Zeno rank certificate (with the branch-level rank that serves every adversary, where one exists — the demonic face's object — and absent, reported as such, otherwise), the absorption kernel at the working fuel, the closed chain as ordinary continuous-time rows with the self-loop mass thinned by the grain itself, and the closed generator by handing the closure to the chain kit: the square's engine reuse, run producer-side, with the race-then-jump-then-absorb spelling re-derived as an exact differential in the test suite. The relay mechanism is a committed cross-language byte-identity vector, and the API block below quotes its receipted construction. Scheduler quantification is mechanized at the semantics layer (the demonic face above); as for the decision frame, the uniform-over-schedulers story is not yet exercised by a published reproduction target — in workshop fixtures with checker acceptance, the bound above survives quantification verbatim, uniform over an adapted scheduler class, through the same machinery as section 12.13's open leg (one design discharges both), and this entry will say more only when that leg ships — and the certificate campaigns remain fixed-scheduler. Open: that reproduction leg; parallel composition of automata, the frame's own design point; logic closure.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (`crates/mtk-catalogue/src/system/`), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{\begin{array}{c} R \text{ off-diagonal rate entries, as for CTMC} \quad O \text{ action-keyed outcome rows, as for MDP} \\ \hline \varsigma : \langle \text{state, action, prob} \rangle \text{ scheduler rows} \quad \iota? \text{ initial-distribution rows} \end{array}}{\text{MA}(R; O; \varsigma) : \text{System}} \quad \text{S-MA}$$

Both parents' row disciplines apply verbatim: no diagonal rate entry, every outcome row action-keyed (immediate transitions use the decision idiom). The scheduler is declared data in this version; quantification over schedulers is mechanized at the semantics layer (the demonic face's verdict pair), with the published reproduction target the named open leg.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.markovAutomaton`

signature — `ts/src/system.ts`

```
/** S-MA: Markov automaton – rates + action-keyed immediate rows + a
 * scheduler declaration (declared data in v1). */
export const markovAutomaton = profileFactory("markovAutomaton");

/** The derived Markov-automaton fixed-scheduler kit: the sort
 * partition, the Zeno rank certificate (mixed-kernel face, plus the
 * scheduler-free branch-level rank when one exists – the demonic
 * face's one-certificate-for-all object), the absorption kernel at
 * the working fuel, the closed continuous-time chain as ordinary
 * CTMC rows, and the closed chain's generator kit – the mechanized
 * square's engine reuse, run producer-side. Derived, never trusted –
 * the checker re-runs the closure's three storeys. */
export interface MaGenKit {
  readonly markovian: readonly number[];

    readonly prob: string;
  }[];
  readonly closed: CtmcGenKit;
```

```

}

/** Derive the Markov-automaton fixed-scheduler kit from a mechanism
 * declaration and a per-state certificate observable on the
 * Markovian states. Maximal progress (a state with both timed and
 * immediate rows), scheduler discipline (coverage, mass one, support
 * within the enabled pairs), and the immediate-cycle Zeno door all
 * come back as witness-shaped refusals naming their geometry. */
export function maGenKit(
  init: MechanismInit,
  cert: readonly StateVal[],
): Result<MaGenKit, Refusal> {
  const raw = native.sysMaGenKit(mechanism(init).nativeHandle, cert) as
    | { kit: MaGenKit }
    | { refusal: unknown };
  return "refusal" in raw
    ? refused(narrowRefusal<Refusal>(raw.refusal))
    : ok(raw.kit);
}

```

construction — ts/tests/magen-native.test.ts

```

/** The `relay-2s1i` presentation (the committed golden fixture's):
 * Markovian 0 and 1, instantaneous relay 2; state 0 races at rate 2
 * into the relay, which returns a third of the mass under the
 * declared scheduler. */
function relayInit() {
  return {
    rates: [
      { src: 0, dst: 2, rate: "2" },
      { src: 1, dst: 0, rate: "1" },
    ],
    outcomes: [
      { src: 2, action: 0, dst: 0, prob: "1" },
      { src: 2, action: 1, dst: 1, prob: "1" },
    ],
    scheduler: {
      rows: [
        { state: 2, action: 0, prob: "1/3" },
        { state: 2, action: 1, prob: "2/3" },
      ],
    },
    initDist: [{ state: 0, prob: "1" }],
  } as const;
}

```

The quoted construction is the committed relay-2s1i cross-language byte-identity vector's presentation, whose thinned closure the kit tests pin in closed form on both surfaces; the kit's Rust face is `mtk_catalogue::system::ma_gen_kit`.

## Rust `mtk_catalogue::system::presets::MarkovAutomaton::manifest`

signature — crates/mtk-catalogue/src/system/presets.rs

```

    .finish();
MarkovAutomaton::manifest(ma).unwrap();

```

## 12.16 Generalized Stochastic Hybrid Systems

**The frame.** Modes with continuous stochastic dynamics, guarded and forced transitions with resets, spontaneous jumps — the frame of Bujorianu and Lygeros [32], and the frame the System notion was designed around, because a modelling language that cannot host it cannot host the systems this toolkit exists for.

**Profile.** The full manifest complement: drift, diffusion, jump fields, plus guarded transitions (guard slabs, resets, forced marks) across modes. Boundary behaviour is first-class and the uniformity break is recorded rather than smoothed: forced transitions are *domain conditions*, not generator terms. Time: hybrid — jumps are events in real time.

**Semantics.** Extended-generator semantics on segments, with the Dynkin argument staged segmentwise. Switched trajectories make per-point differentiability semantically *false*, so decrease obligations for hybrid rows discharge at an upper Dini derivative — corner- and Zeno-immune, with mechanized rungs for switched flows, an integrated almost-everywhere stratum, and Filippov sliding reduced to per-mode vertex rows, at no new row shape in the checker. Hybrid records are native to the universe’s record structure — resets are zero-duration stage pairs (Definition 9.6) — which is why segmentwise semantics needs no second time axis.

**Status.** Certification: the frame’s namesake example is shipped — a three-mode kiln with three forced guard transitions and resets (one nontrivial and load-bearing: the identity-reset probe refuses), spontaneous spikes, and diffusion in both live modes. Nine sequents, every one an ordinary polynomial inequality over a region through the unmodified stack, yield  $P(\text{overheat}) \leq 671/2048$  from the hot start; the battery includes a diffusion-ablation witness showing the second-order term alone carries the hot mode, and the non-Zeno bridge is discharged by inspection of an acyclic transition structure. Representation: the first instance rows to exercise transitions, resets, and forced marks at all. The composite SDCPN formalism of Everdij and Blom — the 2023 candidate — now carries its own entry (section 12.18): places are Bags of coloured-token Systems, and the per-place colour dynamics are this profile’s. Open: a certified example with guards and resets at  $n \geq 2$  (the kiln is one-dimensional and the encounter systems are single-mode); stochastic reset kernels (deterministic polynomial resets are exercised; distributions enter as finitely many reset legs); curved or interior guard geometry beyond boundary slabs; the ingestion gap; closure.

### Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ ,  $\text{pop}$ , and profile conformance are defined in section 12.1.

$$\frac{\begin{array}{l} \vec{x} \text{ declared state variables} \quad M : \overline{\langle \text{id}, \text{name?}, \text{domain} \rangle} \text{ modes with domain constraints} \\ T : \overline{\langle \text{from\_mode}, \text{to\_mode}, \text{guard}, \text{reset}, \text{forced} \rangle} \text{ guarded transitions} \\ D?, N?, J? \text{ mode-indexed drift, noise-presentation, and jump families} \end{array}}{\text{GSHS}(\vec{x}; M; T) : \text{System}} \quad \text{S-GSHS}$$

Forced transitions are domain conditions rather than generator terms — the uniformity break, recorded as structure.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.gshs`

signature — `ts/src/system.ts`

```
/** S-GSHS: modes with domains + guarded transitions (+ the full
 * continuous complement). */
export const gshs = profileFactory("gshs");
```

construction — `ts/tests/system-native.test.ts`

```
return sys.unwrap(
  sys.gshs({
    name: "kiln-2mode",
    state: [{ id: 0, name: "temp" }],

```

## 12.17 The Bag Former

**The frame.** Not a frame at all — a primitive *System-former*:  $\text{Bag}(S)$  is the System of a varying finite multiset of tokens, each token an instance of the argument System  $S$ . It exists as its own entry because structured-population types (the coloured nets of section 12.18 first among them) want “a place holds finitely many tokens with per-token dynamics” as one reusable construction rather than a per-frame encoding trick.

**Profile.** A countably-indexed switched-mode carrier: mode  $n$  is the  $n$ -fold juxtaposition power of  $S$ ’s state, quotiented by exchange — the canonical-multiset representation at the presentation stratum, the Polish symmetric-power quotient at the semantics stratum. Token creation and destruction are the former’s own variant-crossing switch edges (self-loops between adjacent powers); noise is per-token independent. Monad structure (singleton unit, flatten multiplication) sits at the admissible tier rather than in the rows.

**Semantics.** The former denotes

$$\text{Bag}(S) = \coprod_{n \in \mathbb{N}} S^{\boxplus n} / S_n,$$

and the display is a colimit formula in the semantic universe, not a set-theoretic sum; every operation in it is licensed by the standing structure of Definition 9.15. The power  $S^{\boxplus n}$  is the  $n$ -fold juxtaposition composite of the composition calculus, written with the belief laxator’s symbol because its decoration is the  $n$ -fold  $\boxplus$  of  $S$ ’s belief content (its level-of-inconsistency functional) with itself (Definition 9.44); its state space is the  $n$ -fold product  $X^n$  of the inner System’s state space  $X$  (Definition 9.41), and the empty power is the unit System on the one-point space. The symmetric group acts through the juxtaposition tensor’s symmetries — permutations of the  $n$  interface copies, injective tight isomorphisms of the wiring base, acting on states by coordinate permutation — and  $X^n / S_n$  is the coequalizer of those  $n!$  homeomorphisms in the category of Polish spaces and continuous maps, Polish under the matching metric; the disjoint union over  $n$  is the countable coproduct in the same category, its mass sectors clopen (both licences: the bag widget of Definition 9.15). Equivalently the carrier is the space of integer-valued finite counting measures on  $X$  under the weak topology — portmanteau on small balls around the atoms identifies each mass sector with the corresponding symmetric power, and the matching metric on the mass- $n$  sector is the optimal-matching ( $\infty$ -transport) distance between empirical measures — the presentation through which the creation and destruction rate species acquire their point-process reading. So Bag preserves Polishness of the carrier, and bag-valued places stay inside the record-space semantics the rest of the catalogue assumes, with token creation and destruction as zero-duration variant crossings, exactly as hybrid records carry resets (Definition 9.6).

The imprecise denotation passes through the quotient rather than around it. Bounded continuous observables on  $X^n / S_n$  are exactly the  $S_n$ -invariant ones on  $X^n$  (the quotient topology’s universal property), so the weak topology over the quotient is generated by symmetrized test functions, and pushforward along the quotient map is an affine homeomorphism from the exchangeable (permutation-invariant) subprobabilities on  $X^n$  onto  $\Delta_{\leq 1}(X^n / S_n)$  — injective by symmetrizing test functions, surjective by symmetrizing the lift along the canonical-multiset section. A credal body on the bag carrier is therefore the same thing as an exchangeable credal body on the ordered representation — exchangeability is well-definedness, not a preference — and the profile’s per-token-uniform dynamics and beliefs descend because they are equivariant by construction; invariant certificate observables are the quotient’s observables, which is what the canonicalization discipline of the Status leg realizes at the presentation stratum. Two boundaries, kept sharp: bags are finite — infinite multisets break both presentations, and token counts stay finite along every record by construction — and the colimits here are colimits of *carriers*: the formula lifts to Systems through the former, whose monad structure (singleton unit, flatten multiplication) is stated on the fibre categories of the composition construction at the admissible tier, not as a colimit in them.

**Status.** Representation: shipped — the declaration wraps an inner System, an optional capacity, typed creation/destruction edges, and a stored marking under the canonical-multiset discipline (tokens sorted in the exact coordinatewise-lexicographic order, duplicates adjacent, the count derived as the list’s length; the conformance gates refuse a non-canonical stored value, so preset-accepted declarations carry canonical bytes). Semantics and certification: the rate species of the creation/destruction edges is landed as a typed vocabulary — a creation edge reads aggregate observables (the token count), a destruction edge races per unordered token selection with slot-exchange symmetry checked exactly, and a synced edge declares a fused capability whose one firing law lives on the event-port fusion row — and the first certificates exercise a bag carrier end to end: a marked bag of ordinary-differential-equation tokens compiles by the landed view pair into its single-place zero-arc coloured net (the two constructions are one object, checked to the byte on the shared locus), projects onto the Petri incidence presentation, and carries a certified population invariant through two independent checker lanes, with mutants at the designed loci — a non-canonical stored value refuses, an asymmetric selection rate refuses, and a desynchronized transfer flips both checkers. The billiard table as  $\text{Bag}(\mathbb{R}^4)$  remains the worked example on the road for the colour stratum.

**Adequacy.** The square’s measure-theoretic cell — the ordered representation and the collective marking process present one process — is mechanized, sorry-free, in the toolkit’s Lean tree (`lean/su-functor/`, module `SuFunctor.Adequacy.Bag`). The sorted-representative section of the exchange quotient is measurable under the pushforward  $\sigma$ -algebra from nothing but a linear order on colours with a measurable order graph: each sorted coordinate is an order statistic, a finite minimum of maxima of the unsorted coordinates (`sortTuple_apply_eq_inf_sup`, `measurable_symSec`), so no measurable-selection theorem enters, and ties on the diagonal never demand a choice — monotone presentations of one multiset are unique (`monotone_eq_of_toSym_eq`). On that section, the quotient kernel of an exchange-invariant chain closes the commuting square at every finite horizon by kernel-category algebra alone (`quotKernel_comp_eq`, `iter_intertwine`); the construction is independent of the section chosen (`comap_section_congr`); and the transport assembles on the full shape-indexed carrier, token creation and destruction included, with per-permutation exchange-invariance and invariance under canonicalization interderivable (`bag_transport`, `invariance_iff_perm`). The order-graph hypothesis is discharged for the coordinatewise-lexicographic order on real colour vectors that the stored representation sorts by (`measurableSet_le_lex`) — the tie corner lives exactly there, and it is an instance, not an assumption. What remains at its named home: dynamics preservation for the monad’s unit and multiplication (a process-stratum statement), and the per-shape generator agreement that belongs to the coloured-net stratum of the next section.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ ,  $\text{pop}$ , and profile conformance are defined in section 12.1.

$$\frac{S : \text{System} \quad \text{capacity? a declared population cap} \quad M? \text{ a stored marking}}{L : \langle \text{id, kind, } \Delta, \text{law} \rangle \text{ self-loops, kind} \in \{\text{create, destroy}\} \quad \text{Bag}(S) : \text{System}} \quad \text{S-BAG}$$

$m.\text{bag} = \langle \text{inner, capacity?, self\_loops, marking?} \rangle$ ; each self-loop declares its id (the fusion-reference key), kind (create/destroy), per-firing delta, and firing law — delay with a typed rate basis (per-selection or aggregate), guard, or synced; a stored marking is the canonical sorted token list, its count the list’s length.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted

certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## TypeScript `system.bag`

signature — `ts/src/system.ts`

```
/** S-BAG: the Bag former (primitive System-former over an inner
 * System). */
export const bag = profileFactory("bag");
```

The TS conformance corpus holds no construction through this factory at this preview — the cross-language byte-identity fixtures exercise six profiles, and this one's byte authority is the Rust corpus opposite; the factory takes the same init-object vocabulary as every other profile.

## Rust `mtk_catalogue::system::presets::Bag::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```
preset!(
    /// System Catalogue: Bag former – primitive System-former (the
    /// canonical-multiset carrier over the argument System), not a
    /// frame. The extra gates enforce the former's semantics-bearing
    /// discipline: typed edges (unique ids;  $\delta \geq 1$ ; create reads
    /// aggregates, destroy races per selection, guards select the
    /// hitting token; W1 slot-exchange symmetry on per-selection
    /// rates) and canonical stored markings (arity, canonical
    /// rationals, the unique sorted multiset representative, the
    /// capacity cap).
    Bag, "Bag",
    req = [Bag],
    allowed = [],
    extra = |m| {
        let b = m.bag.as_ref().expect("required by signature");
        let d = inner_state_arity(&b.inner, "bag.inner"?);
        bag_edge_gates(&b.self_loops, d)?;
        if let Some(tokens) = &b.marking {
            bag_marking_gates(tokens, d, b.capacity.as_ref(), "bag.marking"?);
        }
        Ok(())
    }
);
```

construction — `crates/mtk-catalogue/tests/builders.rs`

```

    marking: Some(vec![vec![r(-1, 2)], vec![r(0, 1)], vec![r(0, 1)]]),
  })
  .finish();
Bag::manifest(bag).unwrap();

```

## 12.18 Stochastically and Dynamically Coloured Petri Nets

**The frame.** The SDCPN formalism of Everdij and Blom — the candidate unifier of the 2023 grading — as a first-class entry: Petri-net structure whose tokens carry continuous stochastic colour dynamics. The reading this catalogue commits to is compositional rather than monolithic: *places are Bags, arcs are patterns*. The stance has good company in the categorical net literature — nets opened along place boundaries and composed as cospans [12], coloured nets read as monoidal double functors [172], and individuals-based readings of the token game [140] — though the construction here factors through the catalogue’s own composition patterns rather than through a dedicated category of nets.

**Profile.** Places are Bags of a coloured-token System (section 12.17), each with an optional declared capacity; transitions are per-tuple edge families in three species — delay (a rate law), guard (forced), immediate (cascade glue); ordinary arcs are variant-crossing consume/produce resets with multiplicities, and enabling arcs are per-tuple read-outs. Every arc kind is an instance of an existing composition pattern — with one deliberate exclusion: **inhibitor arcs are not a primitive**. Absence-testing breaks enabledness monotonicity, the free commutative-monoid factoring, and the negation-free character of the chase all at once — a unique upper-bound gate in a lower-bound formalism. What survives is the bounded-locus converse: on a place with declared capacity  $k$ , an inhibitor arc is admissible as a *view* — the complement-place compile, whose elaborator is a named successor: a complement place with mirrored arcs and a weight- $k$  enabling arc under a certified linear place-invariant  $m(P) + m(P') = k$  — and the compile provably cannot extend to an unbounded place, which is why no unbounded inhibitor constructor exists at all.

The vocabulary, enumerated. Places being Bag mechanisms, each arc is a composition shape wiring Bag populations: a transition compiles to a *rendezvous* — one joint jump in the fusion discipline of section 13.10, timed by its active party, the transition species — whose other parties are the incident places’ bag edges, themselves the mode-switching machinery of section 13.3. Of the eleven elements of the founding formalism — the arc kinds, the transition species, and the net-level data — ten map onto the pattern inventory, nothing is added to it, and the eleventh is the inhibitor exclusion above. The tenses matter: the per-Bag edge vocabulary, the read-out wires, and the fusion rows themselves are shipped declaration rows — the fusion primitive now carries a producer surface, and the coloured-net decomposition emits its rows (section 13.10) — while the pattern vocabulary downstream of the primitive still speaks in design tense there, so the compiled artefacts this table calls for are graded in the Status leg below.

| element                   | semantics                                                                                                         | compilation target                                                                                                    |
|---------------------------|-------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------|
| ordinary arc, input face  | one token read into the firing data and removed: variant-crossing reset $n \rightarrow n - 1$ at the source place | a rendezvous party: the source Bag's destroy edge, its reset carried by the joint jump                                |
| ordinary arc, output face | a token produced at the target place, $n \rightarrow n + 1$ , its colour drawn from the firing measure            | a rendezvous party: the target Bag's create edge, spawn direction                                                     |
| enabling arc              | the selected token's colour read by rate, guard, or firing measure; no removal                                    | a passive party: a per-tuple parameter-setting wire (section 13.1) into the timing owner                              |
| enabledness count         | pre-enabling threshold: one token per ordinary and enabling input arc                                             | scope rows on the rendezvous's edge family — a monotone, negation-free count guard                                    |
| inhibitor arc             | pre-enabling gate on absence                                                                                      | not compiled — excluded as a primitive; the bounded-locus view above enters through the complement place's rendezvous |
| delay transition          | rate-driven firing: a per-tuple survivor law raced across enabled tuples                                          | the active party: a rate law timing the joint jump                                                                    |

**Semantics.** Marking spaces are Polish by construction: finitely many places, each a Bag carrier — a finite product of the previous section's colimits, inside the standing structure of Definition 9.15. The correspondence with section 12.16 (SDCPN executions as generalized stochastic hybrid processes, the founding papers' own bridge) enters as a translation between *presentations* — never as the definition of the net's semantics, whose compiled reading remains structural in the net while the flattened object is combinatorially large — and its jump-skeleton stratum is mechanized at the uncoloured grain *and* at the coloured deterministic-firing slice: definedness-premise rows, the commuting-triangle cell, the constructed flattening with its agreement derived, and the composed community-to-community corollary included at both grains (the Adequacy leg below), with the remaining coloured obligations — the hybrid-grain carrier identification and the firing-measure kernels — enumerated by name. The compilation direction is Bag-primary: arcs compile into composition patterns — rendezvous of creation/destruction capabilities — over the places' Bag mechanisms, the zero-arc case being the identity.

**Adequacy (statics, the delay-race face, the immediate/cascade face at all three scheduler readings, and the flattening bridge).** The compositional reading — *places are Bags, arcs are patterns* — is not a slogan: the adequacy square for this frame factors through the composition patterns' own mechanized semantics, and it closes at two strata as of this preview, with the rest staged by name. At the statics stratum the square is whole. Stated self-contained:

**Problem 12.14** (the token-game statics square). A marking assigns each place a finite multiset of token colours. A transition of the inhibitor-free fragment reserves, per place, one token for each ordinary and each enabling input arc (distinct tokens), removes the ordinary ones, keeps the enabling ones, adds fresh tokens per output arc, and feeds every reserved colour into one firing datum along its arc's readout [71]. Compile instead: each place a bag composite (one count wire, a token power per mode, states read modulo exchange), consumption a token-split rename, each colour readout an identification-pattern row. Show the two readings agree: markings of each shape are exactly the compiled states modulo per-place exchange renames, and the token game holds between two markings if and only if compiled states realizing them are

connected by split renames and pattern apex states. Show also that the fragment's token game is upward closed — adding tokens never disables a step — and exhibit the gate that would break it.

*Sketch.* The multiset readout of a compiled state is surjective onto markings of its shape and a complete exchange invariant — two tuples enumerate one multiset exactly when a permutation relates them — so the community's configuration space is the compiled state space modulo exchange, shape by shape. For the firing correspondence, forward: enumerate the reserved and untouched tokens through a chosen index split, and the required states are defined directly through the split; backward: the split decomposes the bag as selected-block plus kept-block (the many-token form of the cons identity), and the pattern apex condition is precisely colour-readout agreement. Upward closure is one line per field — the surplus sits in the untouched remainder — and the gate that breaks it is the zero-test: an inhibitor arc is the unique arc kind whose pre-condition is not upward closed, which is why the fragment's transition type has no constructor for it. The exclusion is a formation restriction with the monotonicity theorem as its warrant, not a lint.

At the finite time-abstract stratum the delay species closes as a square. The community execution races every pre-enabled *ordered* assignment of tokens to input arcs on its own exponential clock [71], so from a bounded uncoloured marking the total intensity to a target is the ordered census — per place, a falling factorial of supply over demand — times the rate, summed over transitions; the compiled rows carry the *unordered* convention, one row per token set, with the arc-multiplicity dictionary  $\prod_p (\text{demand}_p)!$  owned by the compiler. The compile-commutes triangle is therefore not definitional, deliberately: it is the dictionary theorem — falling factorial equals factorial times binomial, per place — and through it the square is the continuous-time jump-chain square instantiated at the race chain, engine reuse with zero new inductions; the initial marking enters through the same square's init rows, and firings whose outcome equals their source are thinned by the off-diagonal row grain, the standard jump-chain convention stated as a receipt. Mechanized end to end (`lean/su-functor/`, modules `SuFunctor.TokenGame` and `SuFunctor.Adequacy.StochasticPetri`): the vertical identification, the firing correspondence, the monotonicity warrant, the census-to-embeddings tie, the dictionary triangle, the reused square, and the thinning receipt.

The immediate species closes as a square at the same stratum, by the Markov-automaton closure consumed as built. A marking that pre-enables an immediate transition is *vanishing* — the community excludes it from the state space of the observed process [71] — and here the exclusion is carried by the type: markings split into tangible and vanishing subtypes, the net compiles to a two-sorted Markov automaton whose Markovian sort is the tangible markings, and a delay row at a vanishing marking is thereby unrepresentable — the maximal-progress priority as the domain type of the rate field. Immediate firings are the automaton's action-keyed branches (point masses at this uncoloured stratum); a declared memoryless scheduler resolves conflicts, so the square is scheduler-generic and dominates the community's randomized choice rule, with the uniform-over-enabled scheduler as the shipped instance; cascade termination is a rank certificate — a rank on vanishing markings that every enabled immediate firing strictly decreases — and the fixed-scheduler closure delivers the reduced tangible chain, with vanishing initial mass pushed through the cascade rather than excluded by premise (when the community's initial-tangibility premise does hold, the initial distribution passes through untouched, as a receipt). Timed rows compile in the same unordered convention as the delay face, so the compile triangle is again the dictionary theorem, one storey up, and the square is the automaton square at the compiled net — five-storey engine reuse, zero new inductions. Mechanized in `SuFunctor.Adequacy.StochasticPetriCascade`: the classified state space, the automaton reading, the enabling-respect discipline and rank certificate, the tangible chain with the initial-tangibility receipt, the compile triangle, the reused square, and controls pinning the uniform conflict split, the thinning of returned cascade mass, and a genuine two-step cascade.

The scheduler-quantified sibling closes beside it — the demonic face of the cascade square, and the point where the automaton donor's certificate does *not* transport. The branch-level Zeno certificate that serves every adversary at the automaton (`FinMA.BranchZenoFree`, section 12.15) is refutable at nets: a *disabled* immediate transition at a vanishing marking compiles to the zero-time no-op it is — a self-loop branch row that no rank can strictly decrease (`not_branchZenoFree_of_disabled`, discharged against the species' shipped control net for every rank at once) — so the demon is instead quantified over the subclass the cascade rank actually certifies: *enabling-respecting* schedulers (`RespScheduler`), the class the community's conflict randomizations inhabit, with the uniform scheduler as its shipped member, a discard scheduler witnessing that the arena is genuinely plural (`arena_plural`), and the compiled admission strengthened to

carry the side condition in the statement (`RespectingRows`) rather than smuggling it through a definitional coincidence. Over that arena the set-valued square closes, as at the decision and automaton frames (sections 12.13 and 12.15): the demonic reading of the compiled, scheduler-free net rows is isomorphic, by an invertible globular cell, to the inclusion of the net's demonic tangible law-set (`ispn_demonic_adequacy`, feeding lemma `ispnDemonicC_iff`), the law-set and its credal presentation are independent of which rank certificate is spent (`demonicTangibleLaws_rank_irrel` and `demonicTangibleCredal_rank_irrel`), the equal-mass slice reconciliation and the uniform-over-adversary verdict pair transport (`ispn_demonic_maxSlice`, `satCredal_lower_ispnDemonicCredal` and its upper twin), and the wiring into the semantic universe's judgment lands as the module's own quartet (`su_ispn_demonic_adequacy` with its mem, bottom, and slice forms). Six storeys of engine reuse, zero new inductions. Mechanized, sorry-free, beside the cascade module (`lean/su-functor/`, module `SuFunctor.Adequacy.StochasticPetriDemonic`); history-dependent adversaries stay outside the arena by definition, exactly as at the automaton.

The set-firing face closes beside them, at the marking stratum. The community fires *non-conflicting simultaneous enablings* together — one transition enabled by several token sets, or several transitions enabled at once, no firing disabling the rest [71] — and the face is driven by one value identity rather than any combinatorial induction: a zero-time chain of single firings whose every step is enabled is *exact* (no truncation fires), so per place its result satisfies “result plus ordinary-input total equals source plus ordinary-output total,” and the right-hand data depend on the firing multiset alone (`chainFire_val`). Order-invariance is then value uniqueness — two enabled enumerations of one multiset land the same marking, with no diamond or permutation induction anywhere (`chainFire_eq_of_enabled`; the pairwise diamond is the two-element corollary) — and on the non-conflicting locus the community's randomized choice rule has nothing left to choose between. The simultaneous composite — remove every ordinary-input token at once, then produce, the community's own firing order — equals the chain in every enabled order under *joint supply* (`chainFire_eq_compositeFire`), and the supply hypothesis is load-bearing in the statement, not merely the proof: two swap-token firings pass one token through a chain and land it unchanged, while the composite would read double (the module's refutation control; the community classifies that pair as conflicting — both sets reserve one token — so the hypothesis carves the rule's own boundary). The reservation precondition renders the community's side condition at the counting stratum — members enabled, consumption jointly supplied, each member's enabling-arc reads fitting the pool no sibling consumes, outcome within capacity (`JointReservation`) — and the scope condition the compositional reduction genuinely demands is explicit: intermediate markings need not interpolate between endpoints, and in the capacity fragment the cheap sufficient condition is headroom — source plus output total within capacity (`setNonConflicting_of_headroom`; a reservation-respecting three-element composite whose producer-first order blocks mid-chain is the control that keeps the hypothesis honest). Under reservation and headroom every enumeration is an enabled chain, all agree, and each equals the composite (`r1r3_composite_adequacy`); multiplicity is native — one transition with  $k$  token sets is a replicated multiset, so the one-transition and several-transition rules are one vocabulary. An enabled immediate's branch row in the compiled automaton is a point mass at its firing, so an enabled chain is an absorption path of the cascade closure as already built: the observed tangible process cannot distinguish the community's one-instant composite from any scheduler's zero-time chain. Mechanized, sorry-free, beside the cascade module (`lean/su-functor/`, module `SuFunctor.Adequacy.StochasticPetriSetFiring`).

The flattening toward the hybrid-process reading (section 12.16) enters as a bridge between presentations, not as a definition, and its jump-skeleton stratum is mechanized — at the uncoloured grain in full, and one colour grain up at the deterministic-firing slice (the coloured paragraph below). The translation's definedness premises are certificate-shaped rows: initial tangibility (no immediate transition enabled at the initial support — decidable, with the closed chain's initial row passing through untouched as a receipt); the invariant token bound in the witness-vector idiom — a positive place weighting that no transition of either species increases, with step soundness for both species, closure under reachability, and an intrinsic per-place bound independent of the declared capacity, which is the clause a flattening at the unbounded grain consumes for the finiteness of its mode roster (a token-creating control net admits *no* witness vector, so the row has teeth); and cascade termination, consumed from the landed rank certificate. The triangle itself is packaged from atom-transport agreement (`flatten_triangle_of_agree`): a flat presentation on an abstract mode carrier that agrees with the scheduler-closed net off-diagonally and initially denotes a constraint isomorphic to the net's compiled reading — an invertible globular cell between two house compiles, with no community semantics and no process construction inside the cell. The agreement is no longer a hypothesis: the flattening is *constructed* for every net and every declared

scheduler at this grain — the community’s own construction, one flattened transition per delay transition, its jump intensity the ordered race census times the rate, its reset the cascade-closed firing kernel — and the agreement law is derived from the construction (rate rows by Fubini regrouping and collapse of the fired-marking indicator; initial rows from the tangibility receipt, consumed not re-proved), so every `_of_agree` consumer downstream is discharged outright and the composed corollary states its conclusion with no agreement hypothesis. The drain-net instance survives as a check on the general definition: the constructed flattening reproduces its hand-written flattening data exactly, off-diagonally and initially (the flattened drain edge carrying the arc-multiplicity dictionary through a two-step cascade-closed reset). The *composed corollary* pastes this cell with the two adequacy squares it bridges — the net square’s cascade face on one side and, on the other, the flattened object’s own square, which at this stratum is the continuous-time chain square, a flattened presentation being a finite chain — so the token-game community law and the flattened execution’s community law are one invertible globular cell apart at every jump horizon, and the same pasting read at the judgment stratum says a law models the flattened compiled presentation exactly when it models the net’s. The demonic and angelic faces transfer verdicts through the same pasting as directed cells at the community grain (sound directions only; no envelope equality is stated), and on the drain-net instance an actual flattened-side computation — the three-mode chain takes its drain edge with probability  $3/4$  — is consumed as net-side verdicts by transport, never recomputation. Graded exactly: this is a finite-jump-skeleton analogue, free of the finite-expected-jumps hypothesis, of Everdij and Blom’s process-level bisimulation — different conclusion, different observational grain, neither result implying the other. The holding-time *data* (the exit-rate family) agrees on both sides; and the time-indexed comparison through transient distributions is now mechanized on the killed trajectory-measure side — the killed construction itself, a prefix-marginal factorization (timed prefix marginals as skeleton prefix law, holding attachment, and clock pairing), and the lift from skeleton-law agreement to equal killed transient reads at every horizon, with mutants refused at four preregistered loci — its grain bridge for consuming the published non-Zeno hypothesis verbatim remaining the named residue. The triangle, the derived agreement, the composed corollary, and the killed time-indexed lift are mechanized in `SuFunctor.Adequacy.StochasticPetriFlatten`, `SuFunctor.Adequacy.StochasticPetriFlattenAgreement`, `SuFunctor.Adequacy.StochasticPetriComposed`, and `QtslAux.KilledTimeIndexed`.

The same story closes one colour grain up, at the deterministic-firing slice. The premise rows carry over with their colour reading — initial tangibility unchanged; the invariant token bound with *colour-indexed* weights, its step soundness reading the consumed and produced colour counts of each transition at each colour vector; cascade termination from the coloured rank certificate — and the one premise the uncoloured development could only name, per-place colour-box discharge, is carried by the formation itself at this fragment: the colour boxes are finite types by construction. The triangle cell is packaged against a flattened presentation on an abstract mode carrier exactly as before (the socket a hybrid-grain carrier identification plugs into), and the flattening is again *constructed*: one flattened transition per delay transition *per colour vector*, its jump intensity the coloured ordered census times the colour-dependent rate, its reset the cascade-closed firing kernel through the coloured cascade, with the agreement derived and the composed corollary stated with no agreement hypothesis — the token-game community law of a coloured net and its flattened execution’s community law, one invertible globular cell apart at every jump horizon, at the deterministic slice. On the control net the certificate is the colour dependence itself: from a one-of-each marking the flattened jump chain drains with probability  $2/5$  and flips back with  $3/5$ , the two branches differing *only* in the colour their selections read — a rate map reading colours, flowing through the flattening into the community law, consumed as a token-game verdict by transport. Mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriColouredComposed`); the hybrid-grain residue stays staged, named below.

The flattened object also admits its hybrid-systems reading, and the corollary composes with it. A finite chain is a general stochastic hybrid system whose modes are its states and whose continuous dynamics are trivial, and the embedding is faithful at the data level: the profile’s total alarm intensity at any flattened point is the chain’s exit rate — through the agreement law, the *coloured net’s own* tangible-chain exit rate — and the GSHS extended generator row of a chart-constant certificate degenerates to the chain’s rate row, for every choice of derivative data. So the martingale-problem square of the hybrid layer is consumed unchanged one more step out: a certificate whose Foster-Lyapunov drift rows hold at the scheduler-closed token-game chain yields the square’s safety and deadline verdicts on the flattened execution — token-game rows in, hybrid-skeleton verdicts out, with the square’s segment-model presentations remaining exactly its own hypothesis shape. On the control net the certificate that is 1 exactly on the two capacity-

truncation modes has nonpositive rows — the census-weighted colour-dependent rates and the truncation edge enter the arithmetic — and the verdict pins the chance of reaching the mode that only truncation produces at zero, with every hypothesis discharged on the halt-control realization. Mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriColouredGshsComposed`); the hybrid-grain reading with genuine continuous colour coordinates stays with the staged residue below.

The angelic face closes the scheduler-reading triple. Liveness-style claims quantify *existentially* — some resolution of the conflicts achieves the claim — and the honest existential reads the radially maximal slice of the credal set, for the same reason the universal lower kind does: the credal presentation is downward closed, so the whole set contains the zero model, and an un-sliced existential would be witnessed by zero for every constraint the zero model satisfies (mechanized as a degeneracy lemma, with the zero-threshold upper-bound event atoms as the concrete family). On an equal-mass family the slice is the family, so the angelic verdict is existential quantification over the enabling-respecting arena (`SatAngelic`, `satAngelic_ispnDemonicCredal`; the operator is generic over unions of rays, so the decision and automaton frames inherit it unchanged whenever wanted). One membership fact yields both directed transfers, with the sense-opposition living at the verdict stratum rather than in any reversed cell: universally certified claims restrict to every arena member, and claims established on a member — the transported flattening’s law included — are angelic witnesses (`ispn_demonic_verdict_to_member`, `flatten_angelic_of_agree`, with the packaging as a directed cell into the slice object; sound directions only, no envelope equality). And the two verdicts genuinely differ on the shipped conflict net: the demonic face’s arena-plurality control is upgraded here to the *law* level — the uniform and always-discard members’ closed path laws differ at jump horizon one, the uniform member jump-stepping to the moved token with probability one while the always-discard member’s closed chain absorbs at the source — so the claim “the drain trajectory carries full weight” is angelically satisfied and demonically refused. Mechanized, sorry-free, closing the module family (`SuFunctor.Adequacy.StochasticPetriAngelic`).

The coloured generator faces are landed at their deterministic (Dirac) slice: per-place finite colour boxes, colour-dependent delay rates, guard predicates read as per-vector cylinders on both species, and deterministic firing measures, with the delay-race and cascade squares closed by the same engine reuse through a per-colour-class multiplicity dictionary, conflict resolution over (transition, colour-vector) pairs, and a degeneracy theorem recovering the uncoloured fragment on the nose at the one-colour instance — mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriColoured`, `SuFunctor.Adequacy.StochasticPetriColouredCascade`). The scheduler-quantification faces ride the same coloured arena: the demonic reading quantifies enabling-respecting adversaries over (transition, colour-vector) pairs — at colour the demon selects *tokens*, not merely transitions, and a single transition’s blocked selections, whether by supply or by guard cylinder, already refute the branch-level Zeno certificate that would have transported the automaton square on the nose — with the set-valued square, the angelic dual, and both directed verdict transfers flowing from one membership lemma; a recolouring control net admitting no cascade rank at all pins the rank hypothesis as substantive rather than decorative. Mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriColouredDemonic`). The firing-measure *kernels* beyond the deterministic slice are mechanized at the delay face, on both axes the formation admits. The uncoloured lift takes the firing outcome to a sub-stochastic kernel on the marking space: the census still kills under-supply, the kernel mass kills blocked and unreachable outcomes — so the race intensity needs no enabling gate at all — and mass deficit is the thinned-firing reading, proven semantically inert by a completion receipt (the deficit moves onto an explicit diagonal self-loop, honestly Markov, and the jump-chain path law does not move). The coloured lift is the founding formalism’s firing measure itself: a mass-one kernel over produced-colour assignments, with supply, capacity, and guard gating each sampled outcome — an infeasible draw is a no-op, thinned by the off-diagonal grain. Both delay-race squares close by the same engine reuse through their multiplicity dictionaries, and the deterministic slice embeds *on the nose*: race chains and compiled rows are equal as structures under the indicator-kernel embedding, and the landed Dirac squares re-derive from the kernel squares through the degeneracy ties alone — mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriKernel`, `SuFunctor.Adequacy.StochasticPetriColouredKernel`). The immediate species follows at the same grain: an enabled immediate firing samples its successor marking from a kernel of conditional mass one — full mass exactly where the transition is enabled, because a sub-stochastic immediate draw’s zero-time no-op would enter the Zeno certificate’s support on an enabled action, where enabling-respect cannot gate it; the rank certificate prices sure termination, not merely almost-sure. The cascade square closes by the same automaton engine, whose branches were distribution-valued all along; the termination certificate widens to the kernel’s whole support, and the

sure-versus-almost-sure boundary is itself machine-checked — a kernel with mass at its own source admits no cascade rank at all, by theorem, and a control net whose cascade terminates almost surely (a geometric stay/leave coin) is formation-expressible and certifiably rank-free. The deterministic slice embeds one storey more strongly than at the delay face: the indicator embedding's Markov automaton is *equal as a structure* to the landed one, so the landed cascade square re-derives by rewriting alone — mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriCascadeKernel`). The produced-colour axis closes the kernel-grain lattice: coloured immediate firing measures — the founding formalism's own — sample the colours an enabled immediate firing produces, from a kernel that reads the reserved colour vector *and the source marking*, with mass one on capacity-feasible outcomes exactly where the pair is enabled. The marking-dependence is forced, not chosen: a marking-independent mixing kernel always meets a jam marking (the mixed colour class full at a produced place, the declared one within capacity) where every semantics breaks — a sub-stochastic row is a Zeno-visible zero-time deficit, a stay-completion is certificate-refused mass at the source, and truncation fabricates successor markings — so the kernel renormalizes where capacity bites, and each sampled outcome rides the same per-outcome supply-and-capacity gate as at the delay face, infeasible cells thinned by the gate as dead data. The termination certificate widens to the kernel's feasible support, the stay/leave coin is refused at colour too, and the deterministic slice again embeds at automaton-structure level, the landed coloured cascade square re-deriving by rewriting alone — mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriColouredCascadeKernel`). The flattening seam then closes the composition: both firing-measure axes ride one formation — the finite discrete skeleton of the stochastic-hybrid net class at kernel grain, delay draws and immediate draws each honestly random — and a delay firing's produced-colour draw, pushed through the token game and closed through the immediate cascade, is a *cascade-closed firing kernel* on tangible markings: the hybrid story's reset object, per transition and colour binding. Its row mass is exactly the capacity-gated delay mass — one wherever capacity does not bite, which is everywhere on the founding formalism's own capacity-free domain — the closed chain's rate rows are precisely the race-weighted sums of these reset rows, so the pure-jump hybrid reading consumes the kernel-grain net through its tangible chain unchanged, and at point-mass kernels on both axes the automaton reproduces the deterministic fragment as a structure, the reset row collapsing to the declared outcome's cascade closure — the deterministic-reset restriction of the flattening recovered as a theorem-level face, not a fence — mechanized, sorry-free (`SuFunctor.Adequacy.StochasticPetriColouredFlattenKernel`). What stays staged, by name: the kernel-valued transition schema on the hybrid side — the profile face that would store these reset kernels per transition, and with it the flattening cell at kernel grain; the guard species (boundary forcing); the coloured flattening's hybrid-grain residue — the colour-vector carrier identification with its padding obligations (the flattening itself, its premise rows, the composed corollary at the deterministic slice, and the pure-jump hybrid-systems reading with its martingale-problem verdicts having landed above); and the exponential time-law stratum, exactly as for the plain continuous-time frame.

**Variadic certificates: one row per Petri transition.** A certificate for a net whose token count is unbounded across runs faces two apparent infinities: unboundedly many token configurations, and — since a transition fires once per eligible token selection — a countably infinite family of transition *instances*, each seemingly demanding its own certificate row. Neither infinity survives contact with the syntax, and the two mechanisms are worth stating separately, because they fail separately when abused.

The state side is the plate discipline of section 10.4: certificates are polynomials in pooled coordinates — token counts  $\vec{k}$  and per-place feature pools  $\vec{s}$  — and obligations are polynomial sequents over  $(\vec{k}, \vec{s})$  with coupling, count, and rounding hypothesis rows, their number and dimension set by the net, never by a marking bound. The transition side rides the same grammar fact (no expression names “the  $i$ -th token,” so transition data depends on selected tokens only through their colours): the per-instance obligations of one Petri transition collapse to a single *footprint sequent* in distinguished-token variables — the selected tuple's colours, the pooled coordinates, the counts — with dimension set by the transition's arity and the feature dictionary. One symbolic row covers every instance at every marking. The countable family was never infinite.

What the collapsed row can *claim* depends on the aggregator, and the dependence is sharp. Write a firing's footprint as (consumed multiset  $X$ , produced multiset  $Y$ ), and consider a certificate value that is a *commutative-monoid fold* of per-token features — the fold structure is itself load-bearing: an arity-normalized aggregate such as a mean is not one (a birth changes its denominator under every untouched token, so a footprint row can hold with equality while the ambient value rises), and for such aggregates

only the direct polytope form above applies, never a footprint row. For *safety* rows (the aggregate does not increase), monotonicity of the fold's translations suffices, at every token count: the footprint row “the produced contribution is bounded by the consumed contribution” transfers to the whole marking by one monotone translation, births and deaths included (for signed features the death row is no longer automatic — a death whose consumed contribution is negative is *refused* unless a guard excludes it: a refusal, not an unsoundness). For *progress* rows the conditions are strictly stronger, and each is necessary — drop one and a finite countermodel follows:

- the per-firing decrease must carry a fixed rational gap  $\delta > 0$ , stated in the row — strict decrease alone certifies nothing (halve one token's value forever: every step strictly drops, the run is infinite, the value never reaches its floor);
- the gap must be stated in a scale where the fold is a *translated sum* — for sum-pools the footprint gap row transfers verbatim, uniformly in the marking; a mean fails twice over (no locality, as above, and a per-argument modulus of  $\delta/n$  at  $n$  tokens, so no uniform gap survives an unbounded token count);
- a floor row (the aggregate bounded below on reachable markings) must be discharged — with signed features and token births, every footprint row can hold while progress-rowed firings continue forever down an unbounded descent;
- and *idempotent folds are progress-incapable in every scale*: for max-aggregated certificates the footprint gap fails to move the aggregate whenever an untouched token dominates (two tokens of equal value; fire on one), a regenerating two-transition net keeps the max constant through infinitely many gap-verified firings while the corresponding sum-row is falsified — the sum correctly refuses a certificate the max would wave through — and no strictly monotone change of scale repairs this, since max is a fixed point of conjugation. Max-aggregated certificates certify safety but support no footprint-only progress row against arbitrary ambient tokens (structural anti-masking conditions — a singleton place, a guard consuming every maximal token — are a different and dearer certificate species, not this row); a footprint gap row on an idempotent fold is a formation error, not a modelling choice.

The positive family is correspondingly wide: for any strictly increasing  $\varphi$  on the feature range, the  $\varphi$ -conjugated sum  $\varphi^{-1}(\sum_t \varphi(v_t))$  — the unnormalized  $\ell_p$  folds at  $\varphi(x) = x^p$  over nonnegative features, interpolating from sum ( $p = 1$ ) toward max ( $p \rightarrow \infty$ ); log-sum-exp for  $\varphi(x) = e^{\beta x}$  (with the empty marking sent to  $-\infty$ ) — is strictly monotone in every argument at every finite parameter, which is exactly the property the max endpoint lacks. (The count-normalized *power mean* is deliberately not in the family: normalization re-imports the mean's locality failure.) Progress rows for the family are stated on the  $\varphi$ -space sum (an ordinary pool over the transformed features, with a pinned  $\varphi$ -space gap), where the transfer is uniform in the marking; verdicts transport monotonely for thresholds in  $\varphi$ 's domain (compare  $\sum v_t^p$  against  $t^p$  at  $t \geq 0$  — the checker never computes a root), while the drop measured in aggregate units necessarily shrinks as the *transformed mass*  $\sum_t \varphi(v_t)$  grows, for every superlinear  $\varphi$  — with an explicit rational floor on bounded ranges (for integer  $p$  and aggregate bound  $B$ : at least  $\delta_\varphi/(p B^{p-1})$ ) — which is the reason the  $\varphi$ -space statement is the normative one. For integer  $p$  the transformed features are polynomials and every obligation is an ordinary exact-rational sequent today; non-integer  $p$  and the log-sum-exp family ride the certified enclosure register for transcendental symbols (section 10.5).

Grading, in the book's standard senses: the grammar-equivariance layer is mechanized (the plate modules of section 10.4, including descent to marking-indexed denotations); the pooled compile and the footprint-sequent shape are the shipped row vocabulary of the certificate stratum; the fold-transfer statements above are elementary, each dropped side condition refuted by a finite exact-rational instance (the countermodels of the progress list above), with their formal lemma pack a named, priced successor rather than a landed artefact; the row vocabulary's first exercising campaign at industrial shape is the worked example of chapter 17 (section 17.5). Where the event *count* is itself the claim — expected crossings, Zeno exclusion, deadline tails — the certificate is the crossing budget of the hybrid-process correspondence (section 12.16), not a ranking row; the two prices are different and deliberately not interchangeable.

**Status.** Representation and production: shipped — the declaration vocabulary above is in the conformance corpus, whose worked fixture is a two-place queue/server net with a delay and an immediate transition, ordinary and enabling arcs, and one inhibitor view on a capacity-two place; the view-on-unbounded-place refusal is exercised from both language surfaces. At the uncoloured bounded fragment the squares

certify, the toolkit’s producer surface derives the entire marking-space bridge exactly from the stored net: the bounded marking space under a declared mixed-radix convention (shipped as a decode table, so the index correspondence is checkable), the compiled race rows in the unordered convention with the arc-multiplicity dictionary the compiler owns — the ordered census recomputed as an exact differential in the test suites, the dictionary theorem as arithmetic — the tangible/vanishing sort split with timed rows at tangible sources only (maximal progress as construction), point-mass immediate branches, the declared or uniform-over-enabled scheduler, and the closed observed chain by handing the compiled net to the automaton kit (section 12.15: cascade rank, absorption at the working fuel, vanishing initial mass pushed through the cascade, the initial-tangibility pass-through re-derived as a receipt) or, for the pure-delay net, to the chain kit: the squares’ five-storey engine reuse, run producer-side. The relay-cascade net — whose every delay firing returns through a two-step cascade, thinning the closed chain to nothing — is a committed cross-language byte-identity vector, and the API block below quotes the kit’s surface. The inhibitor view stays outside the compiled fragment by formation (its complement-place elaborator remains the named successor), and per-place capacities, state-dependent rates, and coloured tokens refuse at the kit, each naming its stratum. Semantics and certification: the count stratum has its first certified artefact — a population invariant carried across a transfer rendezvous through two independent checker lanes over a Bag carrier (section 12.17); the token game’s statics square, the delay-race face, the immediate/cascade face — at the declared scheduler and under scheduler quantification alike — and the set-firing face (simultaneous composite firings of non-conflicting immediates) are mechanized (the Adequacy paragraph above), with the coloured generator faces landed at their deterministic slice and the coloured scheduler-quantification faces alongside them, while the guard species (boundary forcing) and the firing-measure kernels beyond the deterministic slice remain the named next legs; net-of-nets composition runs through the token-colouring closure of the composition inventory (section 13.13), with only its shared-place face reserved to the state-sharing axis.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\begin{array}{c}
 \overline{P : \langle \text{id}, \text{name?}, \text{token\_system} : \text{System}, \text{capacity?} \rangle \text{ places}} \\
 T : \langle \text{id}, \text{name?}, \text{species} \rangle \text{ transitions} \quad A : \langle \text{transition}, \text{place}, \text{kind} \rangle \text{ arcs, closed over } P \text{ and } T \\
 M : \langle \text{place}, \text{tokens} \rangle \text{ a stored marking, canonical per place} \\
 \text{every inhibitorView arc's place declares a capacity} \\
 \hline
 \text{SDCPN}(P; T; A; M) : \text{System} \quad \text{S-SDCPN}
 \end{array}$$

`species ::= delay(rate) | immediate | guard`  
`kind ::= consume(k) | produce(k) | enabling(k) | inhibitorView(k)`

The capacity premise is the bounded locus as licence: an inhibitor view on an unbounded place is not a refused edge case but a missing constructor.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx*` or `f.*` are that corpus’s

shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## TypeScript system.sdcpn

signature — ts/src/system.ts

```
/** S-SDCPN: places are Bags, arcs are patterns (the inhibitor VIEW is
 * admissible only on a place with declared capacity). */
export const sdcpn = profileFactory("sdcpn");

        { id: 1, name: "server", tokenSystem: token, capacity: 2 },
      ],
      transitions: [
        { id: 0, name: "arrive", species: { kind: "delay", rate: constant(1, "3/2") } },
        { id: 1, name: "admit", species: { kind: "immediate" } },
      ],
      arcs: [
        { transition: 0, place: 0, kind: { kind: "produce", mult: 1 } },
        { transition: 1, place: 0, kind: { kind: "consume", mult: 1 } },
        { transition: 1, place: 1, kind: { kind: "enabling", mult: 1 } },
        {
          transition: 1,
          place: 1,
          kind: {
            kind: "inhibitorView",
            threshold: 2n,
            invariant: "pinv:server-complement",
          },
        },
      ],
    },
  }),
);

```

The marking-space kit compiles the uncoloured bounded fragment the mechanized square certifies: race rows in the unordered convention (the compiler-owned arc-multiplicity dictionary — the ordered census divided by exactly the dictionary theorem), the tangible/vanishing sort split, point-mass immediate branches, and the closed observed process by engine reuse — the automaton kit where immediate transitions exist, the chain kit otherwise. The kit's Rust face is `mtk_catalogue::system::sdcpn_gen_kit`; its closed-form controls (the census through the dictionary, the two-step cascade with vanishing initial mass pushed through absorption) ride the test suites on both language surfaces.

## 12.19 Shallowly-Embedded Petri Nets

**The frame.** Places, transitions, tokens; the bread-and-butter questions are reachability and coverability of markings.

**Profile.** A shipped theory of its own: places, transitions, and total flow matrices in the incidence presentation (arc multiplicities native, which discharges the “generalized” qualifier of early programme drafts for the arc-weight reading), with markings as first-class elements. Time: none intrinsically — the token game is untimed at this rung; the stochastic and timed wings belong to section 12.16.

**Semantics.** The distinctive entry, and the shallow embedding the section title names: the token game runs *as chase derivation, inside the substrate* — enabledness by negation-free spine walk, firing by successor invention, and marking identity by equality generation, with no oracle in the loop. This is the one frame at this preview whose representation and semantics both run natively in the modelling substrate, rather than beside it.

**Adequacy (the interleaving square, through the compiled route).** The shallow embedding above runs the token game natively; the same untimed frame also enters the catalogue’s *compiled* route, and the adequacy square closes there whole. The compile, in one breath: places become bags of unit-colour tokens — and a bag of unit-colour tokens *is* its count, so markings are count vectors — while each transition becomes one row under the demonic wing of the transition-clock vocabulary (chapter 11) at a strictly positive dwell floor, with a Dirac outcome law, the atomic reset  $m \mapsto m - \text{pre} + \text{post}$ , and enabledness as the arc-cover gate. The compiled semantics is therefore a scheduler-seat family of deterministic timed runs, and its classical corner is not a path law but a relation: the square states that the possibilistic visited-marking face of the family *equals* classical interleaving reachability, for every strictly positive dwell assignment (*face\_eq\_reach*) — the soundness leg spends only enabledness, and the completeness leg realizes each classical firing at exactly the dwell floor. The flagged check comes back quiet: the face is independent of

the dwell assignment (`face_dwell_uniform`), so the uniform unit clock that transcription conventions pin is nowhere load-bearing — the transcription sentence of chapter 11, that the unit-dwell embedding is faithful for ordering-and-counting properties and deliberately not for metric-time properties an untimed net never had, is at this face a theorem rather than a convention’s gloss.

The wiring into the semantic universe lands in the record shape of the demonic corners (sections 12.13 and 12.15, and the scheduler-quantified face of section 12.18): each resolution’s law at a horizon is the Dirac law on its marking trajectory, runs shorter than the horizon idling at their final marking; the compiled presentation is a one-atom projection, so finite presentation is untouched by the resolution family’s infinitude; and the ideal point of a law models the compiled demonic presentation exactly when the law is a member of the demonic law-set (`su_vanilla_demonic_adequacy`, with its `mem`, `bottom`, and `slice` forms). One structural fact is stated in the module rather than dressed up: this species has no rows-level compilation in the tree — every kernel being Dirac, the scheduler seat’s resolutions are the whole mechanism — so the feeding lemma is definitional (`vanillaDemonicC_iff`) and the square’s content lives one retract below the law stratum, at the visited-marking face (`recordVisited_eq_face`). The headline, read at the universe’s judgment: a marking is visited by the support of some law whose ideal point models the presentation, at some horizon, exactly when it is classically reachable (`su_vanilla_reach_iff`) — and the horizon quantifier is honest rather than lossy, since every visited marking is visited at a finite index and prefixes of admissible runs are admissible, so the finite-run family carries the whole reachability face. Dwell-uniformity transports to the same stratum (`su_vanilla_dwell_uniform`), and safety transfers as the customer shape for invariant-class examinations — a marking predicate holds on everything the record semantics can visit precisely when it holds on the classically reachable set (`su_vanilla_safety`) — with one-safeness and unboundedness exercised concretely on a two-place toggle and a one-place source (the dwell floor bounds nothing). Liveness is withheld by design, not staged: the demonic clock carries no fairness, priority, or weight vocabulary, and the idling resolution is always seated, so the honest current semantics asserts reachability and safety, never progress. Set-firing beyond interleaving has its own face at the coloured development (section 12.18); inhibitor arcs and mixed race-plus-demonic systems are untouched at this entry. Mechanized, sorry-free (`lean/su-functor/`, module `SuFunctor.Adequacy.PetriVanilla`).

**Status.** Certification: a three-place producer-consumer ring saturates to exactly its ten-marking state space with coverability verdicts and a place-invariant checked per reachable marking; an overflow mutant is caught by a derived coverability fact, and ablating the equality discipline reproduces divergence as a loud non-termination, not a wrong answer. The hypothesis is stated in the theory itself, not in a side note: token counts live on a finite declared ladder, so fixpoint verdicts are decisions only up to that headroom — exact for structurally bounded nets, while unbounded nets refuse loudly and coverability positives remain semi-decidable witnesses. Semantics: the compiled route’s interleaving square — reachability, dwell-uniformity, and the safety transfer — is mechanized (the Adequacy paragraph above), with no certificate rows minted by the square itself. Open: the ladder-horizon side conditions pinned to their oracle; net-of-nets composition, which runs through the token-colouring closure of the composition inventory (section 13.13) via the coloured wing; the stochastic wing.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , `pop`, and profile conformance are defined in section 12.1.

$$\frac{\text{places, transitions declared finite sets} \quad \text{pre, post total flow matrices over places} \times \text{transitions} \quad \text{marking a first-class marking over places}}{\text{Petri}(\text{places}; \text{transitions}; \text{pre}; \text{post}; \text{marking}) : \text{System}} \quad \text{S-PETRI}$$

The incidence presentation, multiplicities native; totality over the declared sets is closedness consumed as a sort — every flow and marking entry names a declared place and transition by construction.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named fx\_\* or f.\* are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

signature — ts/src/system.ts

```
/** S-PETRI: places, transitions, total flow matrices, marking (token
 * game as chase derivation). */
export const petri = profileFactory("petri");
```

construction — ts/tests/system-native.test.ts

```
// Petri flow row citing an undeclared endpoint: which endpoint.
const dangling = sys.petri({
  petri: {
    places: [{ id: 0 }],
    transitions: [{ id: 0 }],
    pre: [{ place: 7, transition: 0, mult: 1 }],
  },
});
assert.ok(!dangling.ok);
```

The TS corpus exercises this factory through its refusal geometry (the corpus's discipline that failure geometry is routing advice); the quoted construction is that witness, and the happy-path byte authority is the Rust corpus opposite.

### Rust mtk\_catalogue::system::presets::Petri::manifest

signature — crates/mtk-catalogue/src/system/presets.rs

```
preset!(
  /// System Catalogue: Petri net – places, transitions, total flow
  /// matrices, marking (token game as chase derivation).
  Petri, "Petri net",

  })
  .finish();
Petri::manifest(petri).unwrap();

```

## 12.20 Probabilistic Graphical Models

The thesis lists three sub-frames — Bayesian networks, structural causal models, and Markov random fields — and the inventory carries the first and third through *one* rendering: probabilistic dependency graphs (Richardson and Halpern [209]) as wires over trivial dynamics, one wire per conditional table. Dependency graphs strictly subsume Bayesian networks and factor graphs, and here the subsumption is a *checked* sentence rather than a cited one: the classic sprinkler network is reproduced byte-identically through the dependency-graph rendering by two decorrelated pipelines, and a two-source graph certified *inconsistent* witnesses strictly-beyond-network capability — every network-image graph is exactly consistent, so a certified inconsistency is a certified exit from the network image. Structural causal models carry their own theory, below. All three sub-frames are static, and for each the supervisory-switch pattern (section 13.3) is inapplicable — the omission earned by argument from the frame’s own semantics, as the closure leg requires, rather than declared. The pattern’s composition data — per-location executions, a firing moment at which a trajectory reaches a guard, an exit state read at the source and initial data planted at the target — has no instantiation from a semantics whose denotation is a single static measure over joint assignments: a guard over such variables has a truth-value *distribution*, not a trajectory of truth values, so nothing ever fires. The rows can always be typed — wrap the variables as a zero-drift carrier and write a guard box — but the resulting composite denotes switched executions, which is no graphical model: any instantiation exits the frame’s semantic category before it composes. Interventions are no counterexample (model surgery selected by the query, never an event fired when a state condition becomes true), and temporal extensions — dynamic Bayesian networks, samplers run as chains — are different frames, with Markov-chain machinery, where switch composition is applicable and required.

### Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (crates/mtk-catalogue/src/system/), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{W : \overrightarrow{\text{StochasticWire}}}{\text{PDG}(W) : \text{System}} \text{ S-PDG}$$

$$\text{StochasticWire} ::= \text{conditional}(\text{sources}, \text{target}, \overrightarrow{(\text{given}, \text{outcome}, \text{prob})}) \\ | \text{potential}(\text{vars}, \overrightarrow{(\text{assignment}, \text{weight})})$$

One wire per conditional table; potential wires are raw nonnegative tables with no normalization row (their local scale derived, never stored) — the atom that carries Markov random fields through the same species.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.pdg`

signature — `ts/src/system.ts`

```
/** S-PDG: BN / MRF / PDG – stochastic wires over trivial dynamics. */
export const pdg = profileFactory("pdg");
```

The TS conformance corpus holds no construction through this factory at this preview — the cross-language byte-identity fixtures exercise six profiles, and this one's byte authority is the Rust corpus opposite; the factory takes the same init-object vocabulary as every other profile.

### Rust `mtk_catalogue::system::presets::Pdg::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```
preset!(
    /// System Catalogue: BN / MRF (factor graph) / PDG –
    /// probabilistic-dependency wires over trivial dynamics (the
    /// stochastic-wire species); strictly subsumes Bayesian networks
    /// and factor graphs.
    Pdg, "PDG",
    req = [StochasticWires],
    allowed = [],
    extra = ok
);
```

construction — `crates/mtk-catalogue/tests/builders.rs`

```
let pdg = MechanismBuilder::new()
    .stochastic_wire(StochasticWire::Conditional {
        id: 0,
        sources: vec![0],
        target: 1,
        rows: vec![CondRow {
            given: vec![0],
            outcome: 1,
            prob: r(1, 1),
        }],
    })
    .stochastic_wire(StochasticWire::Potential {
        id: 1,
        vars: vec![0, 1],
        rows: vec![PotRow {
            assignment: vec![0, 0],
            weight: r(7, 2),
        }],
    })
    .build();
```

```

    .finish();
    Pdg::manifest(pdg).unwrap();

```

### 12.20.1 Bayesian Networks

**The frame.** Directed acyclic dependency structure with conditional probability tables; the bread-and-butter question is a posterior, which is to say *conditioning*.

**Profile.** Conditional-table wires over finite variables; the joint is the wires' product. Sum-product inference is semiring tensor contraction [198], lowered to contraction rows (the same contraction discipline the substrate reference chapter specifies), and the well-formedness side condition on contractions turns out to be the shape-level shadow of table normalization.

**Semantics.** The joint distribution, exact at finite carrier; the scoring semantics of the dependency-graph rendering recovers it as the consistent case. The rendering's score is, in the universe's terms, a belief (level-of-inconsistency functional) — Definition 9.17 names this incompatibility score as one of its two sources — and the consistent case is its zero locus.

**Adequacy.** The compilation above is not merely well-typed; it is *adequate*: compiling and then denoting in the semantic universe agrees with interpreting classically and then including the classical object into the universe's precise face — the first such square off the time-line, with the topological order of the variables playing the role the horizon plays for chains. Stated self-contained, at the working scale of an exam problem:

**Problem 12.15** (the chain-rule square). Let  $X_0, \dots, X_n$  be finitely many variables with finite value domains, listed in a topological order: each  $X_i$  has a parent set  $\text{Pa}_i \subseteq \{X_j : j < i\}$ , and carries a rational conditional probability table  $P_i(\cdot \mid \text{pa})$ , one row per parent assignment, each row summing to one. On the record space  $\Omega$  of joint assignments write  $\mu_B$  for the chain-rule joint,

$$\mu_B(\sigma) = \prod_{i \leq n} P_i(\sigma_i \mid \sigma|_{\text{Pa}_i}),$$

the factorization semantics of Bayesian networks [141, 196]. Say a subprobability mass function  $\mu$  on  $\Omega$  satisfies the compiled wires when (i) for every  $\sigma$ , the mass of  $\{\sigma' : \sigma'_0 = \sigma_0\}$  equals the sourceless first wire's stored row  $P_0(\sigma_0)$ , an absent row read as 0; and (ii) for every later variable  $i$  and every  $\sigma$ , writing  $C_i(\sigma)$  for the event that a record agrees with  $\sigma$  at all variables of index  $< i$ , refinement by one variable spends exactly one stored row:  $\mu(C_{i+1}(\sigma)) = \mu(C_i(\sigma)) \cdot P_i(\sigma_i \mid \sigma|_{\text{Pa}_i})$ , an absent row again read as 0 — a constraint family whose multiplier reads only the parent coordinates, i.e. the ordered Markov property with the stored tables. Show that  $\mu$  satisfies the compiled wires if and only if  $\mu = \mu_B$  — in particular the constraints force total mass one, so the ambient subprobability slack is never taken up.

*Sketch.* ( $\Leftarrow$ ) Downward induction from full depth gives the closed form  $\mu_B(C_i(\sigma)) = \prod_{j < i} P_j(\sigma_j \mid \sigma|_{\text{Pa}_j})$ : partition  $C_i(\sigma)$  by the value at variable  $i$  and spend one row sum per variable — the multiplier is well-defined because parents sit strictly below the refinement frontier. ( $\Rightarrow$ ) Upward induction along the order pins  $\mu(C_i(\sigma))$  to the same prefix products; at full depth the prefix events are the atoms  $\{\sigma\}$ , so all weights agree, and summing the atoms puts the total mass at one. Two structural remarks carry content: domain nonemptiness is derived, not assumed — the row-sum obligation at a parentless root is over the (inhabited) empty parent assignment, and normalization forces inhabited domains upward along the order — and the constraint family depends on the chosen topological order while the law it pins does not, so every topological presentation of one network denotes the same joint.

In the universe's terms: the constraint family, read as a formal conjunction — one atom per stored wire, in topological order — is the compiled system's denotation at the per-element stratum of the credal stack, and the theorem says this loose arrow is isomorphic, by an invertible globular cell of the thin double category of per-element constraints, to the singleton inclusion of  $\mu_B$ : the precise face of Remark 9.22, whose ray form agrees with the singleton on the radially maximal slice that the verdict operators read. The pointwise equivalence is the chain rule for Bayesian networks mechanized as a pinning statement. The statement and both directions are mechanized, sorry-free, in the toolkit's Lean tree (`lean/su-functor/`, module

`SuFunctor.Adequacy.Pgm`): the pointwise equivalence is `satAtoms_iff`, the invertible cell is `pgm_adequacy`, and the mass identity is `jointLaw_mass`. The same module ties the exact-rational law to the standard monadic construction — ancestral sampling, the variables drawn in topological order by iterated `PMF.bind` against their conditional distributions — as `ancestralPMF_eq`, so the classical side of the square is the community’s mechanized object rather than a private restatement; the inclusion vocabulary is shared with the sibling frames of this catalogue (`SuFunctor.Adequacy.Inclusions`). The square covers the conditional-table face of the species — exactly the Bayesian-network sub-frame of this section; potential wires carry no normalization row, so their inclusion routes through a global normalization fact (the Gibbs distribution of the Markov-random-field sub-frame below) and is deliberately a separate statement.

**Status.** Certification, finite corner: exact-rational posterior certificates with an independent checker and a mutant battery, positivity of the evidence mass checked as a row rather than assumed — on the sprinkler network,  $P(\text{Rain} \mid \text{Wet}) = 509/719$  exactly. Representation: the network as dependency-graph rows, with the posterior recomputed from the rendering’s own minimizer masses [211] and accepted byte-identically by the unmodified network checker. Open: the continuous, score-carrying case — certified conditioning beyond finite enumeration is the named frontier this row shares with section 12.21 — and native ingestion.

## 12.20.2 Structural Causal Models

**The frame.** Structural equations over endogenous variables driven by exogenous sources; the questions that make the frame are interventional and *counterfactual*.

**Profile.** A shipped theory extending the value vocabulary: equations as polynomial rows; an intervention as mechanism surgery — a partial replacement function over equations; and the coupling of counterfactual worlds *structural* rather than disciplinary: one exogenous table per model, so the independent-worlds misreading of a counterfactual is unrepresentable, not merely discouraged.

**Semantics.** Twin-world substitution in the standard (Pearl [195]) sense — diagrammatic modern form in Lorenz and Tull [167] — with the lightest bridge set on the list: substitution, box-measure monotonicity and additivity, and a union bound — no stochastic analysis anywhere. The bridge set is machine-checked, sorry-free, as module `Qtsl.ScmTwin` in the toolkit’s Lean tree: twin-network substitution proven outright for acyclic models, with the box-measure and union-bound lemmas stated as the certificate classes the certifications below instantiate.

**Status.** Certification, in both truth directions, on the thesis’s own flagship specification — a bound on the probability of counterfactually caused harm, at the thesis’s stated  $10^{-4}$  threshold: one controller certified compliant (with the “would have been harmed anyway” cells genuinely exercised), a second certified *in violation* with a two-sided bracket  $3/256 \leq P \leq 17/256$  — inner boxes make violation certifiable, not merely non-certifiable — and a decoupling probe certifying that the same compliant system under the independent-worlds product reading admits  $P \geq 1/2048$ : the frame’s defining distinction, priced by certificates on both sides. Representation: the first instance rows to represent interventions and counterfactual coupling at all. Open: conditioning (counterfactuals given evidence — the full abduction step, joining the frontier named in section 12.20.1); latent confounders and non-Markovian structure (representable, unexercised); non-uniform exogenous densities; the ingestion gap; closure — for which the natural witness is a dependency-wire coupling of an exogenous block to a dynamical frame.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{U : \text{ExogenousTable} \quad E : \overrightarrow{\langle \text{var}, \text{rhs} \rangle} \text{ equations, each rhs polynomial} \quad I? : \overrightarrow{\langle \text{var}, \text{replacement}? \rangle} \text{ interventions (mechanism surgery)}}{\text{SCM}(E; U) : \text{System}} \text{ S-SCM}$$

The exogenous table is an *option, not a list* — one per mechanism, by the sort of  $U$ , which is the structural fact the twin-world pattern of chapter 13 leans on.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.scm`

signature — `ts/src/system.ts`

```
/** S-SCM: polynomial equations + interventions + the shared exogenous
 * table (structural: one per mechanism, by type). */
export const scm = profileFactory("scm");
```

The TS conformance corpus holds no construction through this factory at this preview — the cross-language byte-identity fixtures exercise six profiles, and this one’s byte authority is the Rust corpus opposite; the factory takes the same init-object vocabulary as every other profile.

### Rust `mtk_catalogue::system::presets::Scm::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```
preset!(
    /// System Catalogue: SCM — equations as polynomial rows,
    /// interventions as mechanism surgery, and the shared exogenous
    /// table STRUCTURAL (one per mechanism, by type).
    Scm, "SCM",
    req = [Equations, Exogenous],
    allowed = [Interventions],
    extra = ok
);
```

construction — `crates/mtk-catalogue/tests/builders.rs`

```
let scm = MechanismBuilder::new()
    .equation(0, mono(2, 1, 1, r(2, 1)))
    .intervention(InterventionRow {
        var: 0,
        replacement: Some(constant(2, r(0, 1))),
    })
    .exogenous(ExogenousTable {
        vars: vec![ExoVar {
            id: 1,
            name: Some("u".to_owned()),
            dist: Some(ExoDist::Discrete {
                rows: vec![
                    DiscreteWeight {
                        value: r(0, 1),
                        prob: r(1, 2),
                    },
                    DiscreteWeight {
                        value: r(1, 1),
                        prob: r(1, 2),
                    },
                ],
            })
        }],
    })
```

```

    },
    },
  },
  .finish();
Scm::manifest(scm).unwrap();

```

### 12.20.3 Markov Random Fields

**The frame.** Undirected factor graphs with unnormalized potentials; the bread-and-butter certified quantity is the partition function.

**Profile.** The dependency-graph rendering again, plus one new atom: potential wires — raw nonnegative tables with no normalization row, their local scale derived from entries rather than stored. The founding paper’s own factor-graph embedding is carried as instance rows.

**Semantics.** The Gibbs distribution, recovered as the rendering’s optimum at unit weight; the bracket below is, in those terms, a two-sided certificate on the optimal score — cited to the theorems of the founding paper and its loss-function sequel [209, 210] as a named obligation.

**Status.** Certification: a two-sided partition-function bracket  $\ell \leq Z \leq u$  on a small Ising model with all-rational potentials. The lower end is an explicit support list checked against the summed product directly — the support-restricted variational bound with every logarithm cancelled; the upper end is a tree-reweighted (Hölder) forest decomposition checked as a single rational inequality in which the fractional root never appears on the wire. The checker never computes  $Z$ ; test-side brute force confirms the truth sits inside a bracket whose ends lie at  $0.76\times$  and  $2.81\times$  the true value — displayed as measured rather than tuned. The factor-graph image is generically *inconsistent* as a dependency graph, so this sub-frame and section 12.20.1 together exercise both strata of the rendering’s semantics through one species — checked evidence that the unification is a unification, not an economy. Open: contraction-row evaluation of the forest group sums; the continuous case; the ingestion gap; closure.

## 12.21 Probabilistic Programs

**The frame.** Corecursive programs in a functional probabilistic programming language: sample and score, loops, and the measures they denote.

**Profile.** For the discrete-time slice: loops with sample are outcome-row systems, and the published-table campaign of section 12.11 is certified probabilistic-program verification for that slice — the swept objects are programs, including programs with piecewise-linear neural components. The general profile (higher-order corecursion, continuous distributions — the slice whose denotational home is the  $\omega$ PAP semantics [118]) is not yet rendered.

**Semantics.** The program’s measure semantics, two-tier: the kernel language denotes in the affine probability monad — the monad fork [57], once merely named here, is resolved, and the affine tier’s composition law is machine-checked, sorry-free, at the finite-outcome stratum: with disjoint noise rosters, the denotation of a sequential composite is the Kleisli composite of the stage denotations (`noiseDenot_seqComp` in module `SuFunctor.Stochastic.NoiseKleisli` of the toolkit’s Lean tree), and the copy-vs-resample separation of chapter 11 is carried positively as `copy_ne_kleisli`: a shared roster provably departs from the Kleisli composite, so the disjointness is content, not bookkeeping — while score-carrying measures enter only at the certificate boundary; conditioning denotes a normalized ratio whose positivity is itself an obligation.

**Status.** The forward, unconditioned slice is in place at the discrete tier, as above — and the former-level square is machine-checked, sorry-free: a program’s loop denotes stage kernels, the unrolled program text denotes the kernel-local Kleisli iterate of those kernels at every horizon (`noiseDenot_progTraj`, unconditional

at the finite-outcome stratum, every measurable stage admitted), and for a program whose stage kernels have exact-rational faces the semantic universe’s judgment on the compiled outcome-row presentation pins exactly the unrolled text’s denotation (`su_pprog_adequacy` in module `SuFunctor.Adequacy.ProbProg`) — so the formation rule below sharing the chain former’s data is a theorem-backed reading, not an analogy. Conditioning — posterior bounds for the operation most probabilistic programs exist to perform — is the named frontier, problem statement in hand, shared with section 12.20.1; the published yardsticks are the guaranteed posterior bounds for universal programs [19] and for discrete programs with loops [245]. *The large-language-model clause*: the thesis’s gloss (“including, notably, autoregressive large language models”) gets a scope statement rather than a status. In the small, the clause is subsumable today — a toy autoregressive sampler is a discrete-time chain over token prefixes, and section 12.11’s machinery applies verbatim. In the sense the thesis intends — certified claims about the checkpoints people actually run — it is a programme-scale undertaking well beyond this inventory, and this chapter declines to price it as a backlog row. Stating that plainly is this entry’s content.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ ,  $\text{pop}$ , and profile conformance are defined in section 12.1.

$$\frac{O \text{ unkeyed outcome rows, as for DTMC} \quad \iota? \text{ initial-distribution rows} \quad \tau? : \text{TickDecl}}{\text{ProbProg}(O) : \text{System}} \quad \text{S-PPROG}$$

Deliberately the chain former’s formation data verbatim: the discrete-time slice of a probabilistic program is an outcome-row kernel, and what distinguishes this entry is its reading (the mechanism presents a program’s loop) plus the named open leg — program-as-rows, the corecursive source itself as first-class data, which no premise above carries yet.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.probProg`

signature — `ts/src/system.ts`

```
/** S-PPROG: probabilistic program, discrete-time slice (a loop with
 * `sample` is a kernel, riding the outcome-row machinery). */
export const probProg = profileFactory("probProg");
```

The TS conformance corpus holds no construction through this factory at this preview — the cross-language byte-identity fixtures exercise six profiles, and this one’s byte authority is the Rust corpus opposite; the factory takes the same init-object vocabulary as every other profile.

### Rust `mtk_catalogue::system::presets::ProbProg::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```

preset!(
  /// System Catalogue: probabilistic program, discrete-time slice –
  /// a loop with `sample` is a kernel, riding the outcome-row
  /// machinery. Program-as-rows representation (the corecursive
  /// source as first-class data) is deliberately open; neural
  /// components
  /// ride the hypernet route.
  ProbProg, "probabilistic program",
  req = [Outcomes],
  allowed = [InitDist, Tick],
  extra = |m| outcomes_keyed("probabilistic program", m, false)
);

```

The discrete-time slice rides the outcome-row machinery; the corpus's construction of that machinery is the DTMC fixture, and no ProbProg-preset construction is in the conformance corpus at this preview.

## 12.22 Probabilistic Logic Programs

**The frame.** Definite clauses plus probabilistic facts; the distribution semantics — a measure over least models induced by independent fact coins — and certified brackets on a query's success probability.

**Profile.** Intended: probabilistic facts and clauses as rows over the substrate's own chase — which is already a geometric, Horn-clause engine — with derivation weights in a declared ordered-semiring algebra [174].

**Semantics.** Sato-style distribution semantics. What the frame adds beyond weighted derivations is the *independence structure* of the fact coins: derivations share coin outcomes, so query mass is a sum of products with shared variables, not a free semiring sum — and exactly there, certified *bounds* rather than exact weighted model counting become the achievable target.

**Status.** The frame integration — facts and clauses as rows over the substrate's own chase — remains unshipped, and the frame is graded absent on exactly that line: adjacent code, however promising, does not lift a frame out of absent (that line is what makes these statuses checkable). What the toolkit does carry is the stratum below: the declaration profile (the API block after the metanotation) and, over it, a producer-side certificate species — `problog-v0`, a certified bracket on a query's success probability computed from producer-found explanation and cut rows — whose own API block closes this section. The structural proximity noted above stands: the weight-algebra code exists, and wiring it into the chase is a named seam of the substrate rather than a research question.

### Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (`crates/mtk-catalogue/src/system/`), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , `pop`, and profile conformance are defined in section 12.1.

$$\frac{F : \langle \text{atom}, \text{weight}, \text{coin?} \rangle \text{ weighted facts} \quad \text{semiring a declared ordered semiring} \quad \text{program\_digest? a content-addressed program reference}}{\text{ProbLog(semiring; } F) : \text{System}} \quad \text{S-PROBLOG}$$

The coin index is the independence structure: derivations sharing a coin share its outcome, which is exactly what makes bounds rather than free semiring sums the achievable target.

### API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a

native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## TypeScript `system.problog`

signature — `ts/src/system.ts`

```
/** S-PROBLOG: weighted logic programs over a declared ordered
 * semiring. */
export const problog = profileFactory("problog");
```

construction — `ts/tests/problog-native.test.ts`

```
return sys.problog({
  weightedProgram: {
    semiring: "probability",
    facts,
    programDigest: sha256(SMOKERS_SOURCE),
  },
});
```

facts are the smokers fixture's weighted rows (stress and influence facts sharing declared coins), built beside the quoted lines; the system constructed here feeds the certificate corpus's `fromSystem` path, whose emitted bytes are verified against the committed golden vectors.

## Rust `mtk_catalogue::system::presets::ProbLog::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```
preset!(
  /// System Catalogue: ProbLog / weighted logic programs – the
  /// chase over a declared ordered-semiring weight algebra +
  /// independence structure of fact coins.
  ProbLog, "ProbLog",
  req = [WeightedProgram],
  allowed = [],
  extra = ok
);
```

construction — `crates/mtk-catalogue/tests/builders.rs`

```
let problog = MechanismBuilder::new()
  .weighted_program(WeightedProgramDecl {
    semiring: "probability".to_owned(),
    facts: vec![WeightedFact {
      atom: "edge(a,b)".to_owned(),
      weight: r(3, 5),
      coin: Some(0),
      coin_domain: None,
    }],
    program_digest: None,
  })
  .finish();
ProbLog::manifest(problog).unwrap();
```

## API

Producer surface of the `mtk` toolkit for this certificate species: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

The claims stratum over the S-PROBLOG declaration: a problog-v0 certificate carries the ground program (coin, fact, and clause rows), the producer's search artifacts (explanation and cut rows), and the claimed bracket on the query's success probability — lower by inclusion–exclusion over coin-set unions, upper by min-over-cuts, exact by world enumeration where the coin count permits. The builder verifies every row it is handed (an explanation must derive the query on its own; a cut's joint absence must block it against every other coin) and computes the bracket itself; where the rows came from is the producer's business, and the checker re-derives every claim from the certificate bytes alone.

### TypeScript problog.builder / problog.fromSystem

signature — ts/src/problog.ts

```
/** Start a `problog-v0` certificate for `query` in the probability
 * semiring (declare the ground program with the chainable methods,
 * derive claims with `claimsFromRows`, then `build`). */
export function builder(query: string): CertBuilder {
  return new CertBuilder(new native.PlogCertBuilder(query));
}

/** Derive a certificate builder from a System whose manifest carries
 * the `weightedProgram` family (the S-PROBLOG profile's declaration):
 * coin probabilities come from fact weights (facts sharing a coin
 * must agree – refused with both fact indices otherwise), coinless
 * facts are deterministic and must carry weight 1, and the
 * declaration's program digest is required – it is what pins the
 * grounding correspondence. A System without the family throws
 * (programmer error – wrong manifest kind). */
export function fromSystem(
  system: System,
  clauses: ReadonlyArray<ClauseRow>,
  query: string,
): Result<CertBuilder, Refusal> {
  const r = native.problogBuilderFromManifest(
    system.nativeHandle,
    clausesToNative(closures),
    query,
  );
  return isRefused(r)
    ? refusedResult(narrowRefusal(r.refusal))
    : ok(new CertBuilder(r));
}
```

construction — ts/tests/problog-native.test.ts

```
const b = smokersBuilder(problog, sys);
const claims = problog.unwrap(b.claimsFromRows(ANTICHAIN, CUTS, true));
assert.equal(claims.exact?.toString(), "48861/125000");
assert.equal(claims.lower.toString(), "48861/125000");
assert.equal(claims.upper.toString(), "69/125");
const cert = problog.unwrap(b.build(claims));
```

smokersBuilder and its clause fixture are defined beside the quoted lines; the same file's die-chain exemplar exercises the direct-builder path (builder, mswCoin switch domains) against its own golden vector.

### Rust mtk\_catalogue::system::problog::ProblogCertBuilder

signature — crates/mtk-catalogue/src/system/problog.rs

```
pub fn new(query: impl Into<String>) -> Self

pub fn from_decl(
  decl: &WeightedProgramDecl,
  clauses: Vec<GroundClauseRow>,
  query: impl Into<String>,
) -> Result<Self, ProblogRefusal>

pub fn claims_from_rows(
  &self,
  explanations: Vec<Vec<u32>>,
  cuts: Vec<Vec<u32>>>,
```

```

        with_exact: bool,
    ) -> Result<ProblogClaims, ProblogRefusal>

    pub fn build(self, claims: ProblogClaims) -> Result<ProblogCert, ProblogRefusal>

```

construction — crates/mtk-catalogue/tests/problog\_builders.rs

```

// Manifest stratum: the S-PROBLOG profile accepts the declaration.
let decl = smokers_decl();
let manifest = MechanismBuilder::new()
    .weighted_program(decl.clone())
    .finish();
Problog::manifest(manifest).unwrap();

// Claims stratum: ground the program, hand over the search
// artifacts (explanation and cut rows), and let the builder verify
// them and compute the bracket — lower by inclusion-exclusion over
// coin-set unions, upper by min-over-cuts, exact by enumeration.
let builder = ProblogCertBuilder::from_decl(&decl, smokers_clauses(), "smokes(a)").unwrap();
let claims = builder.claims_from_rows(antichain(), cuts(), true).unwrap();
let cert = builder.build(claims).unwrap();
let bytes = cert.to_cbor().unwrap();

```

smokers\_decl, smokers\_clauses, antichain, and cuts are the corpus's shared fixtures (tests/problog\_common), each re-derived by the reference-number tests beside the quoted construction.

## API

Producer surface of the mtk toolkit for this certificate stratum: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named fx\_\* or f.\* are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

The exact-beyond-enumeration stratum of the problog-v0 certificate: past the world-enumeration cap, the producer commits its search as a leaf-cited decision tree — explanation and cut rows compiled so that every path through the coin axes closes at the first row that decides it, an undecidable cube refusing with the world as witness — and the exact probability is re-derived by the same verify-and-fold walk the checker runs, so the claim never rests on the producer's arithmetic. Both extensions of the wire (the compiled section and the even-depth Bonferroni truncation obligation) are optional and skip-if-absent: every earlier certificate's bytes decode unchanged.

## TypeScript problog.CertBuilder.compiledFromRows

signature — ts/src/problog.ts

```

/** Compile the full compiled section (exact-beyond-enumeration)
 * from producer-found rows: verifies each row, builds the
 * leaf-cited decision tree — refusing, with the undecided world as
 * witness, when the rows cannot decide every cube — and computes
 * `exact` by the same verify-and-fold walk the preflight and the
 * checker run. Attach the result as `claims.compiled` before
 * `build`. */
compiledFromRows(
    explanations: ReadonlyArray<ReadonlyArray<number>>,
    cuts: ReadonlyArray<ReadonlyArray<number>>,
): Result<CompiledSection, Refusal> {
    const r = this.h.compiledFromRows(
        explanations.map((e) => [...e]),
        cuts.map((e) => [...e]),
    );
    return isRefused(r)
        ? refusedResult(narrowRefusal(r.refusal))
        : ok(compiledFromNative(r));
}

```

construction — ts/tests/problog-native.test.ts

```
// The compiled section: producer-found rows (an explanation
// antichain plus cut rows covering every reject cube) compile to a
// leaf-cited decision tree whose exact-rational fold certifies the
// exact query probability with no world-count cap.
const b = dieBuilder(problog);
const compiled = problog.unwrap(
  b.compiledFromRows(DIE_ANTICHAIN, DIE_COMPILED_CUTS),
);
const claims = problog.unwrap(b.claimsFromRows(DIE_ANTICHAIN, DIE_CUTS, true));
const cert = problog.unwrap(b.build({ ...claims, compiled }));
```

dieBuilder and the row fixtures are defined beside the quoted lines; the byte-identity assertion against the committed compiled golden sits directly under the marked construction.

**Rust** mtk\_catalogue::system::problog::ProblogCertBuilder::compiled\_from\_rows

signature — crates/mtk-catalogue/src/system/problog.rs

```
pub fn compiled_from_rows(
    &self,
    explanations: Vec<Vec<u32>>,
    cuts: Vec<Vec<u32>>,
) -> Result<CompiledSection, ProblogRefusal>
```

construction — crates/mtk-catalogue/tests/problog\_compiled.rs

```
// The compiled section: producer-found rows (an explanation
// antichain plus cut rows covering every reject cube) compile to
// a leaf-cited decision tree whose exact-rational fold certifies
// the exact query probability with no world-count cap.
let builder = problog_common::die_builder();
let compiled = builder
  .compiled_from_rows(
    problog_common::die_antichain(),
    problog_common::die_compiled_cuts(),
  )
  .unwrap();
let mut claims = builder
  .claims_from_rows(
    problog_common::die_antichain(),
    problog_common::die_cuts(),
    true,
  )
  .unwrap();
claims.compiled = Some(compiled);
let cert = builder.build(claims).unwrap();
```

the shared fixtures (problog\_common) are the same corpus the claims-stratum block quotes; the hand-built switch-first tree beside the quoted test verifies the same certificate rows against an independent tree layout.

## 12.23 Clocked Boolean Circuits

**The frame.** Synchronous gate-level hardware (and-inverter graphs) as a first-class model type — one of two entries in production use that fall outside the 2023 roster, evidence the inventory is a living catalogue rather than homework against a fixed list.

**Profile.** Circuit content by digest — the ruled content-addressing idiom; gate internals stay un-row-ified — plus boot-prefix rows and per-lane input-configuration rows. Disturbance: demonic inputs as per-lane branch covers. Time: counter, on the machine clock, with a frame counter above it.

**Semantics.** The special case where the checker *is* the semantics: exact replay equivalence, bit for bit; claims read the credal-lower return (Definition 9.21) over the declared branch cover.

**Status.** Certification is the heavy leg: this is the type underneath the hardware-liveness and console campaigns of sections 2.5 and 2.6, where certified minimum-return claims run over branch covers at  $10^7$  ticks. Representation: declaration rows shipped (digest, boot prefix, input configurations). Open: the ingestion gap; closure.

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema's own (`crates/mtk-catalogue/src/system/`), and the former's mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{\text{digest a content-addressed circuit reference} \quad B : \overline{\langle \text{tick, wire, value} \rangle} \text{ boot-prefix rows} \quad C : \overline{\langle \text{lane, wire, value} \rangle} \text{ input-configuration rows} \quad \tau? : \text{TickDecl}}{\text{Circuit}(\text{digest}) : \text{System}} \quad \text{S-CIRCUIT}$$

Gate internals stay un-row-ified — content addressing is the ruled idiom, and the digest names the whole gate graph.

## API

Producer surface of the mtk toolkit for this model type: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.circuit`

signature — `ts/src/system.ts`

```
/** S-CIRCUIT: clocked boolean circuit (AIG by digest; exact replay IS
 * the semantics). */
export const circuit = profileFactory("circuit");
```

The TS conformance corpus holds no construction through this factory at this preview — the cross-language byte-identity fixtures exercise six profiles, and this one's byte authority is the Rust corpus opposite; the factory takes the same init-object vocabulary as every other profile.

### Rust `mtk_catalogue::system::presets::Circuit::manifest`

signature — `crates/mtk-catalogue/src/system/presets.rs`

```
preset!(
    /// System Catalogue: clocked boolean circuit (AIG by digest) –
    /// content-addressed circuit + boot-prefix rows +
    /// input-configuration rows; exact replay IS the semantics.
    Circuit, "clocked circuit",
    req = [Circuit],
    allowed = [Tick],
    extra = ok
);
```

construction — `crates/mtk-catalogue/tests/builders.rs`

```

let circuit = MechanismBuilder::new()
  .circuit(CircuitDecl {
    digest: vec![0xAB; 32],
    boot_prefix: vec![BootRow {
      tick: 0,
      wire: 0,
      value: true,
    }],
    input_configs: vec![InputConfigRow {
      lane: 0,
      wire: 1,
      value: false,
    }],
  })
  .finish();
Circuit::manifest(circuit).unwrap();

```

## 12.24 The i.i.d. Tier

**The entry.** Not a profile — a claim class that every sampleable model type carries, and the second production entry beyond the 2023 list. Where a system’s rollouts can be executed but no analytic species reaches its semantics — a compiled physics engine is the paradigm case — the catalogue switches to *confidence-qualified* judgments: claims of the form “the expected return of this pinned artefact is at least  $B$ , with confidence  $1 - \alpha$ ” (species U5 of section 2.1, always displayed as their own class, never mixed into a table of exact rows). The tier’s name states its subject: a pinned, *closed* composite, sampled under its own law episode after episode — independent and identically distributed draws of the artefact itself. This is the tier behind the physics-engine results of section 2.4, and it composes with the profile inventory rather than competing with it: the analytic tiers take over exactly where a frame’s rows stop being samples and start being algebra.

**The claim form is more general than it looks.** The expectation floor on a bounded per-episode output is the tier’s normal form, and claims that sound set-shaped compile into it. “The next landing stays inside the pad region with probability at least 0.99” is the statement that the mean of the landing indicator is at least 0.99; a quantile bound is a coverage bound at a fixed threshold, hence again an indicator mean; and a bound on a conditional value-at-risk is an expectation floor on a derived output — exhibiting any threshold  $z$  with  $z + \mathbb{E}[(X - z)^+]/(1 - \beta) \leq c$  certifies  $\text{CVaR}_\beta(X) \leq c$ , by the variational form of Rockafellar and Uryasev [213]. What the producer must arrange is that the property’s verdict or score be computed *inside* the sampled composite — the property logic wired in as one more component, its terminal output the episode’s return — and every claim above is then one expectation floor, carried by one certificate species.

**The guarantee class.** The certificates are anytime-valid lower confidence bounds in the game-theoretic school of sequential inference [207]: a betting martingale — concretely, the hedged-capital process for bounded means of Waudby-Smith and Ramdas [237] — is run over the recorded rollouts, the certificate is the resulting wealth ledger, sound by Ville’s inequality [234], and the checker replays the entire ledger in directed-rounding fixed point. This is not a new trust principle beside the rest of the book but the same one in a second mode: the supermartingale certificates of the analytic tiers *prove* the Ville bound against a known kernel, while this tier’s ledger *wagers* it against whatever law would violate the claim — the wealth process is a nonnegative supermartingale under every violating law by construction of the bets, so observed wealth crossing  $1/\alpha$  rejects every such law at confidence  $1 - \alpha$ , at any stopping time, with no penalty for peeking and none for extending the ledger. That anytime validity is what makes the certificate a stable public artefact rather than a frozen experiment, and the betting form is what an independent checker can re-verify line by line; sound statistical model checking [30] is the nearest published genre.

**The conformal sibling.** Conformal prediction [236] — lately including accept/reject guarantees for generative samplers under the name *conformal sampling* [161] — is the same distribution-free finite-sample school under a *weaker* assumption, exchangeability of the draws, with a different validity mechanism: rank statistics of a completed calibration batch, exact at a calibration size fixed in advance. The relation is precise. At the level of claims, a conformal coverage guarantee is an indicator-mean floor, so under this tier’s

stronger sampling assumption the ledger certifies the same statements — anytime-valid, and conditionally on the fitted predictor rather than on average over calibration draws. At the level of mechanisms the two are genuinely different: no adapted betting process can be simultaneously powerful under exchangeability alone — for binary sequences, a nonnegative supermartingale valid under every exchangeable law stays a supermartingale over their closed fork-convex hull, which contains every law on such sequences [208] — and this tier does not attempt that regime. It does not need to: its subject is a pinned closed artefact whose independent resampling is realized by the harness and attested on the certificate, not assumed of nature — the situation in which the stronger assumption costs nothing.

**Pinning.** A confidence bound on “the expected return of this artefact” means something only if there is one fixed law being sampled, and pinning is that premise made auditable — three ordinary ingredients rather than one new trust primitive. First, closure: the sampled composite has no dangling inputs, because an open system has no episode law to sample. Second, identity: trust rows name the sampled artefact by content digest — the policy and its determinism — the same content-addressing idiom the circuit former rules. Third, the one genuinely statistical residue, the sampling-law witness: the attestation that the deployed harness draws independent episodes of the digest-named artefact, with the seed provenance of every source of randomness as its evidence. All three are stated on the face of the certificate, never hidden; ledger production itself lives with the sampling harness rather than in these rows, and the almost-sure return range the martingale requires is itself a certified lemma about the environment’s code, not an assumption (Table 2.5).

## Computer Science Metanotation

as realized in the mechanized toolkit: the family vocabulary is the manifest schema’s own (`crates/mtk-catalogue/src/system/`), and the former’s mechanized ground truth is quoted in the API block below — the producer signatures and, for profile entries, the preset signature naming the populated families — extracted from the toolkit sources at every regeneration of this catalogue, so the two cannot drift apart silently. The formation rule here is typeset by hand for notational quality;  $\Sigma$ , pop, and profile conformance are defined in section 12.1.

$$\frac{\text{rows} : \overline{\langle \text{kind}, \text{detail?}, \text{digest?} \rangle} \text{ trust rows}}{\langle \text{rows} \rangle : \text{PinningDecl}} \quad \text{S-STAT}$$

Not a System former at this preview:  $\text{pinning} \in \Sigma$ , so the family is substrate, admitted alongside every former above, and the confidence-qualified judgment applies to any sampleable type whose subject is pinned. The catalogue’s design direction is for the sampled subject itself to become a first-class construction — a replication former on closed composites, in the Bag former’s genus, whose formation premise is the closure ingredient above and whose trust seam is exactly these rows; it enters the formal inventory with its producer surface, not before.

## API

Producer surface of the mtk toolkit for this entry: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript `system.PinningDecl`

signature — `ts/src/system.ts`

```
export interface PinningDecl {
  readonly rows: ReadonlyArray<TrustRow>;
}
```

```
export interface TrustRow {
  readonly kind: string;
  readonly detail?: string;
  readonly digest?: string;
}
```

Pinning is deliberately not a profile: any sampleable mechanism carries it, and the corpus holds no pinned construction at this preview — ledger production lives with the sampling harness.

**Rust** `mtk_catalogue::system::MechanismBuilder::pinning`

signature — `crates/mtk-catalogue/src/system/manifest.rs`

```
| pub fn pinning(mut self, p: PinningDecl) -> Self
```

Pinning is deliberately not a preset (any sampleable profile carries the family); the corpus holds no pinned construction at this preview — ledger production lives with the sampling harness.

## 12.25 Quantum Nets

**The frame.** Algebraic quantum field theory in its locally covariant formulation, at the kinematic fragment whose mechanization chapter 9 presents (section 9.2): observables indexed by causal diamonds, as they have been since Haag and Kastler [103]; an isotone net of local algebras with Einstein causality and the time-slice property, per Brunetti, Fredenhagen, and Verch [29]; and a positive record family whose Born rows are the measured content. The grade comes first, because a reader who hears “locally covariant quantum field theory” will expect type-III von Neumann algebras, microlocal spectrum conditions, and the continuum. This entry works at a deliberately finite stratum — a finite site, matrix algebras, the kinematic axioms, exact arithmetic — and “fragment” does the same work in this section that it does in the Lean names. Genuine dynamics (relative Cauchy evolution, the stress-energy tensor) lives on the far side of the fragment’s fence, which is where the locally covariant literature itself places it [76], and Fewster and Verch proved that “locally covariant” does not by itself mean “the same physics in all spacetimes” [77]. The bread-and-butter question is a certified bound on record probabilities holding uniformly over every admissible state, and the uniformity is no modelling flourish: the credal face below inherits it from the community’s own state doctrine. A two-qubit example runs through the section, with records the four projectors of the joint computational-basis measurement, so that the record index is a pair of bits: the Bell state prices the row  $(\frac{1}{2}, 0, 0, \frac{1}{2})$ , and the maximally mixed state prices  $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ .

**Profile.** A site kit — finitely many points with their chronology; diamonds, covers, and a distinguished ambient window are derived — with a per-window algebra presentation at matrix grade, generating families entered in  $\mathbb{Q}[i]$ ; matter data (worldlines, jointly exhaustive factors, a reversible mechanism), from which Cauchy determinacy follows as a theorem rather than a postulate; a declared record family at the ambient window — finitely many positive-semidefinite matrices summing to one, a positive operator-valued measure — and a state face, declaring either one distinguished state (the precise face) or a set of states (the credal face), each state carried with the exact-rational witness of its Born row. The carrier is the record space of the declared family, never the algebra: the  $C^*$ -algebra is presentation-tier data, as a Lagrangian is, and what the semantic universe consumes is its gauge-invariant shadow — probability rows over record outcomes. Initial conditions live in the state face.

**Sited time.** Every counter-time entry in this catalogue composes into real time through a tick declaration (section 12.2). This entry needs none: its windows are the site’s own causal diamonds, so the time semantics is the causal order itself — the ground storey of the semantic universe (section 9.1) — and a separate tick would have nothing to declare. Among the values the catalogue’s time-semantics column has needed so far (continuous, counter, hybrid), this one is new: sited.

**Semantics.** The record law of Gell-Mann and Hartle [86], which at a single window is the Born rule: a state  $\rho$  prices the record  $\alpha$  at  $\text{Re tr}(\rho R_\alpha)$ . The mechanized form of that law is the fragment’s own record shadow, so the bridge between the community’s formula and the toolkit’s is definitional rather than analytic; the connector lemma below is one line. Two doctrines from the locally covariant literature

enter as structure rather than gloss. First, the semantics factors through the state object: two states with the same restrictions at the ambient window price every record identically, so the square's left edge is a function of the state-presheaf fibre, as §5.1 of Brunetti–Fredenhagen–Verch demands [29]. Second, the state object is set-valued from birth: a functorial choice of single states is unrealizable — a theorem of the framework [29], re-proven model-independently under dynamical locality [77] — and the replacement that literature adopted, the folium, is structurally the flat shadow of this book's credal bodies (section 9.2 tells that story in full). The well-formedness hypotheses the squares consume are the community's own axioms: isotony, Einstein causality, the time-slice property at its two tiers, record positivity and exhaustiveness, state positivity and normalization.

**Adequacy (precise face).** The compilation stores the Born row and nothing else, so the square is the catalogue's leanest, and its textbook corner is unlike any other in the roster: every other entry's community-facing corner was built for its square, while this one consumes the mechanized fragment verbatim, because the fragment's fields already are the community's axioms. Stated self-contained, at exam scale:

**Problem 12.16** (the quantum-net square). Let  $\kappa$  be a finite record index,  $R: \kappa \rightarrow M_n(\mathbb{C})$  a family of positive-semidefinite matrices with  $\sum_{\alpha} R_{\alpha} = 1$ , and  $\rho \in M_n(\mathbb{C})$  a state: positive semidefinite, of trace one. Store the Born row as exact rationals,  $q: \kappa \rightarrow \mathbb{Q}$  with  $q_{\alpha} = \text{Re tr}(\rho R_{\alpha})$ , and say a subprobability mass function  $\mu$  on  $\kappa$  satisfies the compiled rows when  $\mu\{\alpha\} = q_{\alpha}$  for every  $\alpha$ . Show: (i)  $q$  is a probability row — every entry nonnegative, total mass one; (ii)  $\mu$  satisfies the compiled rows if and only if  $q$  is its weight function, and the uniqueness direction consumes neither an induction nor the exhaustiveness of  $R$ ; (iii) storing only a subfamily  $J \subseteq \kappa$  yields a row of mass  $\sum_{\alpha \in J} q_{\alpha}$  — exhibit an instance of mass exactly  $\frac{3}{4}$ ; (iv) positivity cannot be dropped: exhibit a Hermitian family summing to one, and a state, that together price an outcome negatively.

*Sketch.* (i) The trace of a product of positive-semidefinite matrices is real and nonnegative, and linearity spends the two normalizations:  $\sum_{\alpha} \text{Re tr}(\rho R_{\alpha}) = \text{Re tr}(\rho) = 1$ . (ii) The singleton probes read off every weight directly, and two subprobability mass functions with equal weights are equal — finite extensionality and nothing more. Compare the chain square (Problem 12.8), whose uniqueness runs an induction along the horizon and spends a row sum per step; exhaustiveness enters here only through the mass claim of (i). (iii) Sum the stored subfamily; for the instance, take the maximally mixed two-qubit state against three of the four basis projectors:  $3 \cdot \frac{1}{4} = \frac{3}{4}$ . (iv) One dimension suffices: the family  $(2, -1)$  on  $M_1(\mathbb{C})$  sums to one, and the unique state prices the second outcome at  $-1$ .

In the universe's terms: the compiled rows denote one probability-pinning constraint per record index, their formal conjunction a loose arrow at the per-element stratum of the credal stack, and the theorem exhibits an invertible globular cell to the singleton inclusion of the Born row — the precise face of Remark 9.22. The statement and both directions are mechanized, sorry-free, in the toolkit's Lean tree (`lean/su-functor/`, module `SuFunctor.Adequacy.QuantumNet`): the invertible cell is `quantum_net_adequacy`, the pointwise equivalence is `satAtoms_iff`, and the presentation structure (`QNetSystem`) consumes the fragment (`LCQFTFragment`, module `QtslAux.QuantumAssembly`) verbatim, together with a distinguished state and its exact-rational row witness. The community tie is cheaper here than anywhere else in the catalogue, and the entry says why rather than dressing it as more: the connector `shadowPMF_prob_eq_born` is the row witness itself — the mechanized record shadow is the literature's formula transcribed — and the mechanized probability library has no quantum machinery for a deeper tie to borrow, where the chain square could tie into the library's own monadic construction. What replaces depth is doctrine: `shadowPMF_eq_fragment_shadow` and `shadowPMF_class_invariant` factor the left edge through the state-presheaf fibre at the ambient window, so the classical semantics consumes the Brunetti–Fredenhagen–Verch state object rather than a bare density matrix. The mass theorems are `shadowLaw_mass` and `rowsLaw_mass_of_complete`, and the two-qubit instances tie to the fragment's landed shadows by `rfl(bellQNet_shadowPMF, mixedQNet_shadowPMF)`. Task (iii) is a first for the catalogue: the target stratum has carried a mass-loss allowance from birth, every stochastic entry's constraints force mass one (the chain problem says so explicitly), and `exists_incomplete_mass_lt_one` — three of the four projectors at the maximally mixed state — is the first compiled row set to exercise the allowance: an incomplete record family denotes a genuine subprobability law. Task (iv) is `exists_nonPSD_family_negative_shadow`, the kernel-visible reason record positivity appears among the hypotheses. The square also re-reads as a citizenship statement in the semantic universe's fibre over a one-wire record interface, by pushforward along the record embedding (`su_qnet_adequacy`); the wiring pattern is the assignment interface's, reused verbatim.

**Adequacy (credal face).** Every other imprecise face in this catalogue is chosen: a modeller declares a parameter box, or quantifies over policies or schedulers, because caution recommends it. Here the set-valuedness is a theorem of the frame's own literature — a functorial choice of single states is unrealizable [29, 77] — so the state face of a quantum-net presentation declares a set of states because the theory has nothing narrower to declare. Stated self-contained, at exam scale:

**Problem 12.17** (the credal square). Data as in Problem 12.16, except the state face: in place of one  $\rho$ , a set  $S$  of states is declared, and a *member witness* is a state of  $S$  together with the exact-rational row of its Born values. Write  $D$  for the set of member Born rows. On the compiled side the rows stay state-free: say  $\mu$  is *admitted* when the compiled rows of *some* member witness are satisfied by  $\mu$ . Show: (i)  $\mu$  is admitted if and only if  $\mu \in D$ ; (ii) every member's row has mass one, so the downward-closed credal presentation generated by the members' rays has  $D$  as its radially maximal slice, and both verdict polarities read as bounds uniform over every member; (iii) if  $S$  is closed under rational convex mixture then  $D$  is closed under rational mixtures of member rows, and the hypothesis is necessary: over the two-element set consisting of the Bell state and the maximally mixed state, the midpoint of the two rows prices the double-zero record at  $\frac{3}{8}$ , and no member does; (iv) record the degeneracies — with at least one member witness, the whole-set reading of a lower-bound atom refuses every positive threshold, and with none, both verdict kinds pass vacuously.

*Sketch.* (i) is the precise face's feeding lemma, run once per member, under the union of singletons. (ii) The record family's exhaustiveness prices every member at mass one, and the equal-mass reconciliation is the automaton problem's (Problem 12.13), reused. (iii) A quantum mixture's Born row is the same rational mixture of the members' rows, by linearity of the trace, so mixture-closure of  $S$  pushes to convexity of  $D$ ; for the negative half, the member witnesses pin the double-zero entry to  $\frac{1}{2}$  and  $\frac{1}{4}$ , and  $\frac{3}{8}$  is neither. (iv) The zero model lies on every ray, and a universal quantifier over an empty member index holds vacuously.

In the universe's terms: the admitted-by-some-member reading of the state-free compiled rows and the union-of-singletons inclusion of  $D$  are isomorphic by an invertible globular cell, exactly as at the decision and automaton formers — but where those faces quantify over an adversary the modeller invited, this one quantifies over the physics. The statement and both directions are mechanized, sorry-free, in the same module: the invertible cell is `quantum_credal_adequacy`, with admission predicate `qnetCredalC` and feeding lemma `qnetCredalC_iff` over member witnesses `RatShadowMember` (a member is carried with its certificate, never bare); the slice reconciliation is `quantum_maxSlice`, packaged as a cell by `quantum_ray_singleton_reconciliation`; the verdict transfers at both polarities are `satCredal_lower_quantumCredal` and `satCredal_upper_quantumCredal`, with law-set twins; the convexity theorem is `quantumLaws_mix`, consuming the fragment's mixture seam (`recordShadowPMF_mix`), with negative witness `mixLaw_not_mem_pair`; and the degeneracies are `not_satCredal_upper_quantumCredal_geC` and `satCredal_quantum_of_isEmpty`, recorded rather than smoothed. One more degeneracy is quoted deliberately: at matrix grade the folium is flat — every linear functional that is unital and positive on rank-one projectors is represented by a unique density matrix (`Qtsl.QuantumStates.existsUnique_isState_traceRepr`) — so this face's content lives in the set-valuedness and the credal band, never in folium distinctions; the strict openness of the Bell/mixed band is the fragment's `exists_shadow_lowerE_lt_upperE`. Deliberately separate strata, stated once: multi-window histories through the class-operator machinery of `QtslAux.QuantumRecords`, the named stretch tier; the quasilocal stratum, where folium distinctions become real and the algebras stop being matrix algebras; and dynamics beyond the kinematic fragment — relative Cauchy evolution and the stress-energy tensor [76] — outside this square by hypothesis rather than silently discharged.

**Refinement and abstraction.** The two squares above relate a System to its community semantics; this passage's statement-kind relates a System to a System. The community doctrine being transposed is effective field theory, and the grade comes first once more: a reader who hears the phrase will expect loop integrals, power counting, renormalization-group flow, and the continuum, and none of those live at this stratum. What survives the transposition — finite site, matrix algebras, exact arithmetic, kinematics plus one-step dynamics — is the procedure's logic, and the logic turns out to be the certifiable part. As its own standard references present it [34, 197], effective field theory is a two-ingredient move. Coarse-grain exactly: the Wilson action is what remains after the high-energy modes are integrated out once and for all — a pushforward, with nothing approximate about the step [34]. Then truncate with a declared tolerance: the effective theory keeps finitely many operators, their coefficients matched so that its predictions agree

with the pushed-forward theory up to the desired order [197]. An effective theory is never equal to the pushforward; it agrees with it inside a declared band, and the band is part of the statement. The move's reach is why it belongs in a catalogue of certifiable model types at all: it is effective-theory reasoning that justifies neglecting quantum corrections in macroscopic gravity while pricing them systematically [34] — “known physics” at any scale is an effective theory with a band — and a containment certificate is what that kind of validity claim looks like as an artefact.

Both ingredients are already on this entry's shelf, the first as the record-level coarse-graining calculus — record atoms merge along any map of indices, and pushing the law is measuring the merged observable family — and the second as a containment. Write  $d$  for the total-variation distance on outcome rows, half the  $\ell^1$  distance, exact rational at rational rows; inflate a law set by a tolerance  $\varepsilon \in \mathbb{Q}_{\geq 0}$ , admitting every row within distance  $\varepsilon$  of a member. The *certified-abstraction* statement between a fine System and a coarse one, along coarse-graining data  $f$ , is then a containment: every law the fine theory permits, pushed forward along  $f$ , lies in the coarse theory's  $\varepsilon$ -inflated law set. Error bars become imprecision, and “valid to accuracy  $\varepsilon$ ” becomes decidable arithmetic at finite index. Three choices inside that sentence carry the doctrine. The quantifier direction is soundness: the coarse law set may be strictly fatter than the pushforward — that is what “effective” means — but no behaviour the fine theory permits is ruled out, so the abstraction is epistemically honest: the coarse description's uncertainty band covers the fine truth. The tolerance lives on the law set rather than the state set, because matching in the literature is a statement about observables, and the checker's arithmetic lives on rows. And the tolerance is declared, never derived: power counting — the literature's dimensional-analysis estimate of what a given truncation achieves [34] — proposes  $\varepsilon$ , and the containment certificate checks it. Burgess's “Effective-Lagrangian Logic” [34] is a four-step procedure whose middle steps rest on power-counting estimates; here the estimates sit exactly where an untrusted heuristic belongs, in producer-side search, and trust-the-estimate is replaced by check-the-containment.

The worked exhibit is a block spin, and one design point governs its reading: the coarse theory is declared independently of the fine one. Had its presentation been defined as the coarsened fine family, coarse-graining would commute with compilation on the nose — the strict square is a landed theorem (`pushforward_ofPresentation`, module `QtslAux.QuantumCoarseGraining`) — and containment would hold at tolerance zero, exhibiting exact lumping rather than truncation; the effective-theory content is precisely that the declared coarse theory is simpler than the pushforward and provably within the band. Stated self-contained, at exam scale:

**Problem 12.18** (the block-spin containment). Data on the section's running two qubits, records the four joint computational-basis projectors, indexed by pairs of bits. The *fine* state face is the rational segment between the basis state at  $(0, 1)$  and the two-branch state with amplitudes  $\frac{24}{25}$  and  $-\frac{7}{25}$  on  $(0, 0)$  and  $(1, 1)$  — Born rows  $(0, 1, 0, 0)$  and  $(\frac{576}{625}, 0, 0, \frac{49}{625})$  respectively — a mixture-closed set, as the credal square requires; the fine mechanism is the reflection exchanging those two branch vectors, unitary, involutive, and rational-entried because  $7-24-25$  is a Pythagorean triple. The coarse-graining  $f$  keeps the first bit. The *coarse* theory, declared independently: records the two block-spin projectors (the fiber sums of the fine family), state face a single product state with row  $(1, 0)$ , mechanism the identity kernel — the block spin is 0 and nothing evolves. Show: (i) the segment member at parameter  $t$  pushes forward to the row  $(t + (1-t)\frac{576}{625}, (1-t)\frac{49}{625})$ , and containment holds at tolerance  $\frac{49}{625}$ ; (ii) the band is attained — any certifying tolerance is at least  $\frac{49}{625}$  — so containment at  $\varepsilon = 0$  is refuted: the truncation is genuine; (iii) on the mechanism's two-point orbit, the one-step defect — the distance between coarse-graining after one fine step and one coarse step after coarse-graining — equals  $\frac{49}{625}$  at both points, and every horizon  $k$  is then valid within  $k \cdot \frac{49}{625}$ ; (iv) the further merge to a single total record is contained at tolerance zero, and the composite fine-to-block-to-total containment holds at  $\frac{49}{625} + 0$ : budgets add along a tower.

*Sketch.* (i) The pushforward sums fibers and is affine in  $t$ : the first extreme pushes to  $(1, 0)$ , at distance zero, the second to  $(\frac{576}{625}, \frac{49}{625})$ , at distance  $\frac{49}{625}$ , and the member at  $t$  to distance  $(1-t)\frac{49}{625}$ . (ii) The coarse theory offers exactly one row, so the second extreme forces  $\varepsilon \geq \frac{49}{625}$  on any certificate, and a positive rational is not zero. (iii) The reflection swaps the two extreme states, so the pushed rows exchange  $(1, 0)$  and  $(\frac{576}{625}, \frac{49}{625})$  while the identity kernel holds each fixed; both defects are the distance already computed. For the horizon, the coarse step is a row-stochastic kernel, and such kernels contract total variation, so the  $k$ -step distance regroups through the triangle inequality into  $k$  one-step defects. (iv) Every state prices the single total record at trace one, so fine and coarse push to the same point row; merging twice is one merge along the composite map, and the triangle inequality adds the two budgets.

In the universe's terms: a refinement relation between two presentations, whose content at the credal stack is inclusion of law sets after inflation — so verdicts transfer across it with an  $\varepsilon$  margin, in the conservative direction. The vocabulary and the exhibit are mechanized, sorry-free, in the same module family as the squares (module `SuFunctor.Adequacy.QuantumContainment`): the distance is `tvDistQ`, with the metric lemmas and `tvDistQ_eq_zero_iff`; the inflation is `credalInflate`, monotone in the tolerance and in the set and commuting with the union-of-singletons form the credal face compiles; the statement is `Containment`, with monotonicity (`Containment.mono`) and additive vertical composition (`Containment.comp`); the row pushforward is the fiber sum (`SubPMF.map_wt_apply`), contracts the distance (`tvDistQ_map_le`), and measures the merged family (`recordShadow_coarsenFamily`). The exhibit's theorems are `uv_ir_containment`, `uv_ir_containment_lower`, and `not_uv_ir_containment_zero` for tasks (i) and (ii); `onestep_defect` and `horizon_bound`, instantiating the generic `lax_horizon` through the contraction `tvDistQ_stochAct_le`, for task (iii); and `ir_tot_containment` composing to `uv_tot_containment` for task (iv), whose zero leg consumes nothing but conservation of mass. The state face exercises the credal square's own convexity hypothesis (`uvSeg_mixClosed`, consumed by `uvLaws_mix_exercised`), and the two pushforward notions in the tree — Gram submatrix at measure level, fiber sum at row level — agree on the exhibit (`pushforward_probRow_bridge`). The qualitative half of the tower rides along: coarser is more classical, in the monotone sense that off-diagonal mass is antitone along tower legs (`eftTower_offDiagMass_antitone`) — though on this exhibit the dividend is degenerate, since projective records decohere every branch at the fine stage already (`eftStage_classical`); the strict decoherence drop lives on the library's three-stage diamond tower, cited rather than re-proven.

The fences, in the section's own manner. State-space compression, once the first fence here, is discharged at the same finite grade: the block spin whose state space genuinely shrinks lands as an isometry stratum and a trace-preserving Kraus channel with the compression/record-shadow interchange proved channel-wide (`recordShadow_kchanApply`); the partial trace acquires an explicit Kraus certificate (`kchanApply_ptrKraus_eq_ptr`), and the containment certificate transfers verbatim across the compression — the same declared band, still attained, still refuted at zero tolerance (`uv_smallIR_containment`). What stays fenced there is any compression-ratio or optimality claim: which compressions exist or are efficient is producer-side search, never certificate content. No power-counting claim: it enters as producer guidance only, and the checker never consumes an estimate as if it were a theorem. No continuum word: genuine Wilsonian renormalization — loop integrals, continuum limits, scheme independence — and perturbative error control made rigorous are research mathematics on the far side of this fence, and the literature's own error control is perturbative through and through, which is why the mechanized entry point is the finite stratum, where the error is one exact rational and there is no regularization scheme to hide in. What the fences protect is a modest, checkable form of the doctrine the literature itself teaches — every theory in this catalogue is somebody's effective theory [197], and certified budgets add along the descent.

**Status.** Semantics is the strong leg, and unusually strong for an entry this young: the kinematic mathematics (section 9.2) and both adequacy faces are mechanized end to end, with the negative witnesses — dropped positivity, dropped completeness, dropped mixture-closure — carried as theorems beside the positive ones. The refinement statement ships at the same grade — band proved, band attained, zero tolerance refuted — so the mechanized column runs both statement-kinds, System-to-semantics and System-to-System. Representation is design work: no producer surface exists at this preview, and the normative row grain is the adequacy module's own rows structure (`QNetRows`: sparse outcome rows over the record index; well-formedness as nonnegativity plus mass at most one; completeness deliberately separate), which a future declaration vocabulary and producer surface will mirror rather than reinvent. Certification: nothing shipped; the one genuinely open producer-side design point is exact positive-semidefiniteness certification over  $\mathbb{Q}[i]$ , where an exact  $LDL^*$  witness settles the generic case and the boundary-rank convention needs fixing before the first certificate does. Compositional closure: this version is a closed former, with no wiring interface, and the omission is argued from the frame rather than bare-declared — the physically native composition operations are spacelike tensor composition of nets, the named successor, a Composition Patterns sibling whose side condition is Einstein causality; and subregion embedding, which the site already carries internally. The deterministic-PDE entry set the precedent of landing former-level ahead of its composition story, and this entry follows it.

## Computer Science Metanotation

as mechanized in the toolkit's Lean tree: this entry's ground truth is the presentation structure and compiled row grain of its adequacy development (lean/su-functor/, module SuFunctor.Adequacy.QuantumNet, over the fragment structure of QtslAux.QuantumAssembly), rather than a producer extraction. No producer surface exists for this entry at this preview; the API block is omitted rather than invented, and the formation rule below is typeset by hand from the mechanized structure's fields.

$$\frac{K : \text{SiteKit} \quad \overrightarrow{N : \langle \text{window}, \text{gens} \rangle \text{ algebra rows}} \quad M : \text{MatterData} \quad \overrightarrow{R : \langle \text{index}, \text{matrix} \rangle \text{ record rows}} \quad \sigma : \text{StateFace}}{\text{QNet}(K; N; M; R; \sigma) : \text{System}} \text{ S-QNET}$$

The site kit lists finitely many points with their chronology; diamonds, covers, and the ambient window are derived. Algebra rows present one generating family per window, entries in  $\mathbb{Q}[i]$ ; matter data comprises worldlines, jointly exhaustive factors, and a reversible mechanism; record rows live at the ambient window. The state face declares one state with its exact-rational Born row (the precise face) or a set of states, each member carried with its row witness (the credal face). The well-formedness obligations are the community's own axioms — isotony, Einstein causality, the time-slice property, record positivity and exhaustiveness, state positivity and normalization — consumed by the mechanized textbook corner as the fragment's fields.

## 12.26 Future Work

The frames collected here are the catalogue's frontier: no producer surface at this preview — no rows, no API, no certificate. Encodings for some of them are in progress, and will graduate their entries to full catalogue sections as producer surfaces land. They stay in the catalogue as prose entries precisely so the chapter cannot quietly shrink its scope, and each keeps its full four-leg grading; what they do not get is an invented formal block, because a metanotation statement with no mechanized ground truth underneath would be exactly the coverage-matrix-of-green-ticks failure this chapter refuses. The quantum nets of section 12.25 are deliberately not collected here: that entry's semantics and adequacy squares are mechanized end to end, and only its producer surface remains future work.

### 12.26.1 Open Games

**The frame.** Compositional game theory: players, strategy sets, and utilities in the lens-shaped composition structure whose entire point is that games compose.

**Profile.** Intended: the composition structure preserved as the representation's grain — a rendering that flattens an open game to one normal-form matrix would fail the representation leg by construction. Not yet designed in rows.

**Semantics.** Equilibrium semantics under composition; the research content of this row lives here.

**Status.** Nothing shipped; the thesis's own bimatrix analysis is a *use* of game theory, not a subsumption witness, and we decline to count it. The concrete entry road is the certification leg: for polynomial games,  $\varepsilon$ -best-response inequalities are polynomial inequalities over strategy boxes — exactly the shape the kernel decides — so a certified  $\varepsilon$ -Nash artefact is buildable ahead of the representation and semantics legs that carry the real research weight. Graded absent until any leg ships.

### 12.26.2 Mean-Field Games

**The frame.** A representative agent coupled to the distribution of a population of itself; equilibria are forward-backward systems (Hamilton–Jacobi–Bellman backward, Fokker–Planck forward).

**Profile.** Intended: a representative-agent mechanism coupled to a population-distribution state. Not designed in rows.

**Semantics.** The equilibrium system itself; in the master-equation formulation, a PDE system — so the road runs through section 12.5, whose beachhead changes this row’s feasibility without yet shortening it much.

**Status.** Nothing shipped; this cell was not-covered in the 2023 SDCPN grading too, and it remains the list’s structurally hardest entry. The first tractable question is narrower than the frame: certified  $\varepsilon$ -consistency of a *given* candidate equilibrium pair, both components polynomial, may be reachable well before the frame itself. Graded absent.

### 12.26.3 Score-Based Generative Models

**The frame.** Diffusion models read as dynamics: a learned score field is the drift of a reverse-time stochastic differential equation, and the generative process is that equation run from noise.

**Profile.** Intended: an SDE mechanism (section 12.7’s profile) whose drift is a neural network, carried by content-addressed reference with piecewise-linear structure exposed to the kernel the same way the discrete campaigns already exercise.

**Semantics.** The generative path measure, through the same staged generator bridges as section 12.7.

**Status.** Nothing shipped for the frame as such — but this row is a *composite* gap, not a novel one: the multidimensional diffusion machinery is in place, the network-drift representation is in place elsewhere in the stack, and what remains is their composition. Graded absent, with its cost inherited almost entirely from parts that already exist.

## Systems: Composition Patterns

DRAFT

This chapter is the second wing of the System Catalogue — the first, chapter 12, inventories what a single mechanism can be; this one inventories how Systems combine. A specification is only as compositional as the model underneath it, so the System layer ships composition as a small, closed inventory of *patterns*: each is a syntactic row family with a typing rule, a semantics, and an explicit account of which certificates transport across the composite boundary and which are *refused*. The refusals carry real content: per-component stability certificates must not compose to composite stability, because that inference is false (re-entrant lines destabilize below capacity under plausible dispatch policies — Kumar–Seidman and kin [145]), and the pattern inventory encodes the refusal structurally rather than leaving it to the modeller’s vigilance.

A pattern, throughout, is a *usage of the wiring stratum plus its transport rules* — the row-level counterpart of composition by wiring diagram in operadic treatments of dynamical systems [162]. The composition data are ordinary rows — the manifest’s own composite-stratum descriptors, or one of four dedicated pattern row families — and the transport rules that move certificates across a composite boundary are rules of the Rule Catalogue, not machinery of this chapter. Each entry below states the pattern in prose (composition data, transport, witness status), then closes with the same two blocks as every System Catalogue entry. The *Computer Science Metanotation* block gives the entry’s *term former*: an inference rule whose premises are the formation data the pattern builders consume and refuse on, with their sorts, and whose conclusion is a primitive judgment at the sort System — or at the pattern’s own sort, where the mechanized constructor forms a pattern row citing its subjects rather than a System; the four dedicated row families do exactly that, and their rules say so. The *API* block carries producer surfaces extracted from the toolkit sources at every regeneration. Two reading conventions, stated once. First, the wiring-stratum rules display a *single* pattern row in the composite’s row slot: a composite carries any number of rows across the families, with each row’s premises checked independently, and the head form elides the ambient rows. Second, as in the first wing, optional formation data (marked ?) are consumed without appearing in the head form. The first four entries — the three wiring modes and nesting — are the composition machinery that the model-type chapter’s fourth grading leg, compositional closure, checks frames against; the remaining formal entries are instruments with landed witnesses. Two entries near the end withhold their formal blocks, by the same refusal that governs the first wing’s frontier entries: event ports, whose primitive’s producer surface has already landed, and state sharing, reserved outright. Between them sits supervision, whose semantic tier is mechanized ahead of its producer surface — its gating uses an arc kind the inventory already carries. The chapter closes with an entry that records a closure property rather than a pattern.

The composition tier underneath this inventory is mechanized, sorry-free, in the toolkit’s Lean tree (`lean/su-functor/`). The semantic universe’s decoration functor carries its compositor with every coherence obligation proved — transport functoriality, compositor naturality, associativity, and both unit laws, on the nose modulo the base’s definitional transports (module `SuFunctor.SingleSiteSemanticUniverse`) — and the possibilistic inclusion of hypernets composes through it exactly, with no determinism hypothesis (`SuFunctor.HypernetInclusion`). On the content-addressed wire stratum the calculus is strict, and failure is part of the account (module `SuFunctor.HypernetComposition`): composition of aligned interfaces is associative and unital on the nose (`AlignedLoose.seq_assoc` — hierarchy pays no coherence tax, which is the semantic face of the nesting entry’s freeness); components with equal semantic interfaces are interchangeable in any composite (`austereDnf_subst` — the congruence property every entry below presupposes when it speaks of transport across a boundary); an infeasible component makes its composite infeasible (`admRegion_append_empty_left`, iterating along the strict associativity above), while the converse fails by a mechanized witness (`share_contradiction`); and renaming a composite is the composite of the renamings (`theta_rename_seq`), so a certificate transported across a renamed boundary composes to the transported composite. What follows is therefore inventory over a proved foundation, and each entry’s transport story

stands on that tier rather than re-arguing it.

## 13.1 Parameter Setting

One system’s output fixes another’s parameter: an input wire bound to a parameter appearing in the consumer’s field polynomials. This is the “set” mode of the wiring stratum — directed by construction, so the row demands its from endpoint resolve to a declared output and its to endpoint to a declared input wherever the component’s interface is declared. Transport is the assume–guarantee square [38]: the wiring is certified for spec-to-spec entailment with slack, the leaves are ordinary sequents, and the slack arithmetic is checker-recomputed. **Witnessed** — this is the mode behind the inventory’s one cross-frame composition witness (the ODE plant wired to a discrete controller of section 12.4, every mutant of the composite refusing), and behind the inventory’s deliberate asymmetry: one mode witnessed, the rest below graded only as far as their evidence reaches.

### Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum’s own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former’s mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\frac{S_1, \dots, S_k : \text{System} \quad \text{from, to : PortRef into the roster, from} \neq \text{to} \quad \text{dir(from) = output} \quad \text{dir(to) = input}}{\text{Composite}(S_1, \dots, S_k; \langle \text{set, from, to} \rangle) : \text{System}} \text{ S-SET}$$

PortRef =  $\langle \text{component, wire} \rangle$  addresses the roster by index. The direction premises resolve against declared *mechanism* interfaces; an endpoint whose component declares none (a composite; a mechanism without an interface binding) passes to the checker’s replay.

### API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

#### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

#### Rust `mtk_catalogue::compose::CompositeBuilder::set`

signature — `crates/mtk-catalogue/src/compose/builder.rs`

```
pub fn set(mut self, from: PortRef, to: PortRef) -> Self
pub fn build(self) -> Result<SystemManifest, Refusal>
```

construction — `crates/mtk-catalogue/tests/compose_common/mod.rs`

```

CompositeBuilder::new()
  .component(plant())
  .component(controller())
  .set(port(1, 1), port(0, 0))
  .build()
  .expect("set endpoints resolve against the declared interfaces")
  .named("set-loop")

```

## 13.2 Variable Sharing

Two systems read identified wires: the “share” mode identifies its two endpoints as one variable, with direction consumed by the causality check rather than declared in the row (stochastic wires remain directed-only at this preview). Transport: the same assume-guarantee square; the admissible-tier anchor is the small-gain arithmetic witness — the certified composite in which cross-supplies cancel identically. **Status:** machinery staged at the rule level; no heterogeneous share witness has landed yet. The mode’s *semantics*, by contrast, is already theorem-grade: admissibility of an identified composite is the conjunction of the parts’ admissibilities, mechanized with no determinism hypothesis at the catalogue stratum (`glue_admissible_iff`) and the semantic-universe stratum (`admRegion_append`, `theta_comp`); and identification is exactly where feasibility fails to compose — the minimal mechanized witness is a pair of individually feasible constant sources demanding different values of one shared variable (`share_feasible`, `share_contradiction`, module `SuFunctor.HypernetComposition`), while infeasibility, once present, propagates outward through further wiring (`admRegion_append_empty_left`).

### Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum’s own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former’s mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\frac{S_1, \dots, S_k : \text{System} \quad \text{from, to : PortRef into the roster, declared where an interface exists} \quad \text{from} \neq \text{to}}{\text{Composite}(S_1, \dots, S_k; \langle \text{share, from, to} \rangle) : \text{System}} \text{ S-SHARE}$$

The row identifies rather than assigns, which is why, unlike S-SET, no direction premise appears: either side may be an input or an output, and the two wires denote one variable of the composite.

### API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

#### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

**Rust** `mtk_catalogue::compose::CompositeBuilder::share`

signature — `crates/mtk-catalogue/src/compose/builder.rs`

```
pub fn share(mut self, from: PortRef, to: PortRef) -> Self

construction — crates/mtk-catalogue/tests/compose_common/mod.rs

CompositeBuilder::new()
  .component(plant())
  .component(controller())
  .share(port(0, 1), port(1, 0))
  .build()
  .expect("share endpoints resolve against the declared interfaces")
  .named("shared-bus")
```

### 13.3 Mode Switching

A supervisory edge hands the active role between components. Switch edges live at the composite stratum in three species: guarded (guard content at the composite level), rate (stochastic hand-off at a state-dependent intensity — the species that makes switched diffusions composable), and forced (domain-exit at the composite stratum). Transport: the switch-composition rule, staged at the rule level with per-profile soundness lemmas in the inventory. **Status:** rule staged, witnesses pending; the static frames (the graphical-model rows of chapter 12) carry *inapplicability* arguments instead — a frame with no internal time axis has nothing for a supervisory switch to sequence — and that escape is earned per-frame by an argument from the frame’s own semantics (section 12.20 states it), never by a bare declaration.

#### Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum’s own (crates/mtk-catalogue/src/system/compose.rs and the pattern row families of crates/mtk-catalogue/src/compose/), and the former’s mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\frac{S_1, \dots, S_k : \text{System} \quad i, j < k, i \neq j \quad \sigma : \text{species}}{\text{Composite}(S_1, \dots, S_k; \langle i \rightarrow j, \sigma \rangle) : \text{System}} \text{ S-SWITCH}$$

$$\sigma ::= \text{guarded}(\overrightarrow{\text{constraint}}) \mid \text{rate}(\text{poly}) \mid \text{forced}$$

$i \rightarrow j$  names roster indices — the component handing off and the component receiving — and the  $i \neq j$  premise is the no-self-switch refusal. The rate polynomial is exact-rational, like every field polynomial in the catalogue.

#### API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named fx\_\* or f.\* are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

#### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (WiringRow, SwitchEdge, ScheduleAssumption) already ride the TS system namespace (system.composite), while the pattern builders and the four pattern row families are Rust-only at this preview.

**Rust** `mtk_catalogue::compose::CompositeBuilder::switch_guarded`signature — `crates/mtk-catalogue/src/compose/builder.rs`

```
pub fn switch_guarded(
    mut self,
    from_component: u32,
    to_component: u32,
    guard: Vec<DomainConstraint>,
) -> Self

pub fn switch_rate(mut self, from_component: u32, to_component: u32, rate: Poly) -> Self

pub fn switch_forced(mut self, from_component: u32, to_component: u32) -> Self
```

construction — `crates/mtk-catalogue/tests/compose_common/mod.rs`

```
let too_hot = DomainConstraint {
    poly: mono(1, 0, 1, r(1, 1)),
    op: "ge".to_owned(),
    rhs: r(100, 1),
};
CompositeBuilder::new()
    .component(thermal("heater", r(3, 1)))
    .component(thermal("cooler", r(-1, 10)))
    .switch_guarded(0, 1, vec![too_hot])
    .switch_rate(1, 0, constant(1, r(1, 20)))
    .switch_forced(0, 1)
    .build()
    .expect("switch edges cite roster components")
    .named("supervisor")
```

## 13.4 Nesting

Hierarchical composition is free in the theory: a component of a composite is any *System* — a mechanism or a built composite — so composition terms nest by construction, and no dedicated descriptor exists to get out of sync with the term structure. The flatten rule guarantees the discipline’s point: composites add structure and scalability, never expressiveness. Wire-level containment resolves against declared *mechanism* interfaces, and a composite component’s wires pass to the checker’s replay (composites declare no export map at this preview). **Status:** structural (the construction cannot fail to nest), but unwitnessed as a certified heterogeneous artefact; hierarchical control is the named first candidate.

## Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum’s own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former’s mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

No former of its own — deliberately. Nesting is the recursion already present in the core grammar: COMPOSITE’s premises (section 12.1) quantify over *System*, which a built composite inhabits exactly as a mechanism does, so `Composite(..., Composite(...), ...)` is well-formed by the rules already stated — cited here, not restated. A dedicated nesting rule would exist only to drift from the term grammar it duplicates.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s

shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

**Rust** `mtk_catalogue::compose::CompositeBuilder::component`

signature — `crates/mtk-catalogue/src/compose/builder.rs`

```
| pub fn component(mut self, sys: SystemManifest) -> Self
```

construction — `crates/mtk-catalogue/tests/compose_common/mod.rs`

```
| CompositeBuilder::new()
|   .component(set_composite())
|   .component(thermal("watchdog", r(-1, 100)))
|   .switch_forced(1, 0)
|   .build()
|   .expect("nesting is structural")
|   .named("hierarchical")
```

Nesting is structural: `component` accepts any manifest — a mechanism or a built composite — so composition terms nest by construction; no dedicated descriptor exists.

## 13.5 The Hybrid-Time Pattern

The pattern that discharges multi-clock composition in practice: put the discrete component's tick on a timer mechanism, prove the component's rows schedule-generically — per-tick, in its own counter — and carry the schedule class (period bounds, jitter bracket) in the *assumption slot* of the composition square. One value function, one cover, both time semantics — with the price of jitter certified, not assumed. **Witnessed:** the lander free-flight pair of section 12.2 (the same funnel under exact tick and jitter bracket from one table and one cover, jitter costing a certified factor 2.66 in ticks-to-funnel, with two exact infeasibility theorems marking where full dispersion is impossible), checked on an independent lane; the pattern text is the staging-independent recipe. The square behind the recipe is machine-checked, sorry-free, in the toolkit's Lean tree (module `SuFunctor.Adequacy.HybridTime`): compiling the rows onto the coarse clock, versus reading the per-tick semantics back through the declared clock morphism, the walled composite sits on the weak side in general (`hybridTime_square_subset`); the two readings agree whenever the transport relation is a function graph — the pattern's own tick seam is one (`tickSeam_hybridTime_square_eq`) — and at a jittered-coarse seam the inclusion is strict, which is why the assumption slot, and nothing else, carries the price of jitter.

### Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum's own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former's mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\frac{S_1, \dots, S_k : \text{System} \quad i < k \quad \tau : \text{TickDecl}}{\text{Composite}(S_1, \dots, S_k; \langle i, \tau \rangle) : \text{System}} \text{S-HYBTIME}$$

At most one assumption per component — a duplicate is refused with both declarations serialized. `TickDecl` is section 12.2's grammar, here in the assumption slot of the composition square rather than on the mechanism.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

### Rust `mtk_catalogue::compose::CompositeBuilder::schedule`

signature — `crates/mtk-catalogue/src/compose/builder.rs`

```
| pub fn schedule(mut self, component: u32, tick: TickDecl) -> Self
```

construction — `crates/mtk-catalogue/tests/compose_common/mod.rs`

```
CompositeBuilder::new()
    .component(plant())
    .component(controller())
    .share(port(0, 1), port(1, 0))
    .set(port(1, 1), port(0, 0))
    .schedule(
        1,
        TickDecl::Jitter {
            lo: r(9, 100),
            hi: r(11, 100),
        },
    )
    .build()
    .expect("schedule assumption cites a roster component")
    .named("multi-clock")
```

## 13.6 The Funnel Pattern

Transit plus absorbing tail: an outer transit certificate (reach the gate within a budget, worst-case) composed with an inner invariance certificate (the gate region is forward-invariant and its holds are certified), citing the inner region as the outer target through the tower discipline. This is the certified shape of approximate dynamic programming with a terminal set — the outer table a value-supersolution on a cell graph, the inner tail the polynomial telescope. **Witnessed twice:** the pendulum swing-up row (a 24,467-cell supersolution, capture within 139 steps,  $\text{return} \geq -619.99$ , composed with the upright-hold invariance as absorbing tail) and the lander attitude funnel. The sort stated in the block below is forced, not chosen: a funnel that collapsed its parts into a one-slot composite could not be a lawful compositor, because collapsing composition breaks the unit law — a machine-checked refusal (`funnelComp_breaks_unit_coherence`, beside its no-tax counterpart `unitClass_transparent`, module `SuFunctor.Plain.Battery`) — so the pattern composes certificates about a System rather than forming one. The pattern's positive semantics is machine-checked in the same tree, sorry-free (module `SuFunctor.Adequacy.Funnel`): a funnel's composite satisfies the coupled transit-then-hold reading as a pure instantiation of the tower's composition theorem for budget sums with certified dips (`funnel_coupledSat_of_parts`, instantiating `coupledSat_comp_add_of_dips` with no new induction), and the tower-citation edge enters as an equation: assembly succeeds precisely when transit and hold cite one gate (`assemble_isSome_iff`), so a funnel whose parts disagree on the gate is unrepresentable rather than refused at replay.

## Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum's own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former's mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\frac{\text{sys : SysRef} \quad \text{transit, hold : SpecRef} \quad \text{gate : RegionAtom carrying a certified family} \quad \text{budget} \in \mathbb{Q}_{>0}}{\text{Funnel(sys; transit; hold; gate; budget) : FunnelDecl}} \text{ S-FUNNEL}$$

The sort is forced: not a System former — the pattern composes two certificates about one subject System, cited by reference, and its row is the composition data the tower-citation edge consumes at replay. The gate premise excludes the bare box: the tower discipline cites *certified families* (sublevel or affine), and a box region carries none to place the citation on. The budget premise is the sign gate — a funnel with no transit budget asserts nothing about reaching the gate.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

## TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

## Rust `mtk_catalogue::compose::funnel`

signature — `crates/mtk-catalogue/src/compose/funnel.rs`

```
pub fn funnel(
    sys: SysRef,
    transit: SpecRef,
    hold: SpecRef,
    gate: RegionAtom,
    budget: WitRat,
) -> Result<FunnelDecl, Refusal>
```

construction — `crates/mtk-catalogue/tests/compose_common/mod.rs`

```
funnel(
    SysRef("sys:pendulum-swingup".to_owned()),
    SpecRef("spec:transit-to-gate".to_owned()),
    SpecRef("spec:upright-hold".to_owned()),
    RegionAtom::Sublevel {
        cert: CertFamRef("vfam:telescope".to_owned()),
        thr: r(1, 1),
    },
    r(139, 1),
)
.expect("fixture conforms to the funnel pattern")
```

## 13.7 The Twin-World Pattern

Two intervened copies of one model run against a single draw of the exogenous sources — the counterfactual composition. The pattern is *structural*: the causal-model profile owns one exogenous table per mechanism (an option, not a list — section 12.20.2), and the pattern row carries one base mechanism, so the decoupled independent-worlds reading is unrepresentable rather than discouraged. The certified decoupling probe prices exactly what that unrepresentability is worth (0 coupled against  $\geq 1/2048$  decoupled for the same controller). **Witnessed**: the counterfactual harm certificates in both truth directions (section 12.20.2). The pattern’s semantic bridge is machine-checked in the toolkit’s Lean tree (`lean/qlsl/`, module `Qtsl.ScmTwin`): twin-network substitution — the counterfactual event as an ordinary single-network event of the twin model, proven outright for acyclic models — together with the box-measure and union-bound certificate classes the harm certificates instantiate, and the worked instance’s landmark values as drift alarms; a sorry-free development, its axiom census the standard classical base.

### Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum’s own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former’s mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\frac{\text{base : Mechanism} \quad \{ \text{equations, exogenous} \} \subseteq \text{pop}(\text{base}) \quad \text{base un-intervened} \quad \text{left, right : InterventionRow, each var defined by a base equation, no var twice per world}}{\text{TwinWorld}(\text{base; left; right}) : \text{TwinWorldDecl}} \quad \text{S-TWIN}$$

Two facts about the sort, both deliberate. The conclusion is a pattern row, not a System. And the base’s sort is Mechanism, not System: a composite base is unrepresentable, which is the one-exogenous-table structure stated as a premise sort — the coupling is *through* that table. A pre-intervened base is refused (world surgery is this pattern’s own left/right; anything else would smuggle a third world in). An empty intervention list is a legal world — the factual side of a harm query intervenes on one side only.

### API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

#### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

#### Rust `mtk_catalogue::compose::twin_world`

signature — `crates/mtk-catalogue/src/compose/twin.rs`

```
pub fn twin_world(
    base: Mechanism,
    left: Vec<InterventionRow>,
    right: Vec<InterventionRow>,
) -> Result<TwinWorldDecl, Refusal>
```

construction — crates/mtk-catalogue/tests/compose\_common/mod.rs

```
// Variable index space: endogenous x0, x1 then exogenous u (2).
let base = MechanismBuilder::new()
    .equation(0, mono(3, 2, 1, r(1, 1)))
    .equation(1, mono(3, 0, 1, r(1, 2)))
    .exogenous(ExogenousTable {
        vars: vec![ExoVar {
            id: 0,
            name: Some("noise".to_owned()),
            dist: Some(ExoDist::Box {
                region: BoxRegion {
                    axes: vec![[r(-1, 1), r(1, 1)]],
                },
            },
        )],
    })
    .finish();
twin_world(
    base,
    vec![InterventionRow {
        var: 1,
        replacement: Some(constant(3, r(1, 1))),
    }],
    vec![],
)
.expect("fixture conforms to the twin-world pattern")
```

## 13.8 The Stochastic-Wire Pattern

Systems coupled through probabilistic-dependency wires — one conditional-table wire per dependency: the frame family of the graphical-model row (section 12.20) and simultaneously a composition mode for exogenous blocks feeding dynamical frames. Single-system use is landed (the network rendering); **cross-system use awaits the marginal-compatibility discharge**, and the pattern row carries that residue explicitly as data: the citation field for the compatibility certificate is optional, and *empty means pending*. That this residue matters is itself machine-checked: the classical obstruction — pairwise-consistent marginal families with no joint law (Vorob'ev) — is mechanized over the subprobability stock (vorobev\_no\_joint, module SuFunctor.Adequacy.MarginalGlue: not even a mass-losing joint exists), records glue where laws do not (vorobev\_record\_glue), and an inconsistent family denotes the bottom credal object rather than crashing (credalCompile\_vorobevGlue) — so an absent  $\mu$  citation marks a pending composite, never a silently wrong one.

### Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum's own (crates/mtk-catalogue/src/system/compose.rs and the pattern row families of crates/mtk-catalogue/src/compose/), and the former's mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\frac{S_1, \dots, S_k : \text{System} \quad W : \overrightarrow{\text{CrossWire}} \quad \mu? : \text{CertFamRef}}{\text{StochasticCoupling}(S_1, \dots, S_k; W) : \text{StochasticCouplingDecl}} \text{ S-STOCHWIRE}$$

$$\text{CrossWire} = \langle \text{sources} : \overrightarrow{\text{PortRef}}, \text{target} : \text{PortRef}, \text{rows} : \overrightarrow{\langle \text{given}, \text{outcome}, \text{prob} \rangle} \rangle$$

Per-wire formation data, checked wire by wire: sources resolve to outputs and the target to an input where an interface is declared (directed-only at this preview); the target is not among its own sources; each row's given arity equals the source count; an empty source list is a marginal (an exogenous block feeding a frame unconditionally); and — the exact-arithmetic gate — per-given probabilities sum to one, exactly, with

the computed sum as the refusal witness.  $\mu?$  is the marginal-compatibility citation, consumed without appearing in the head form; its absence *is* the pending residue, carried as data. The sort is deliberate: this is the one pattern that consumes Systems without forming one — the coupling is certified composition data over its roster, and the composite System awaits exactly the discharge  $\mu$  cites.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

### Rust `mtk_catalogue::compose::stochastic_coupling`

signature — `crates/mtk-catalogue/src/compose/stochwire.rs`

```
pub fn stochastic_coupling(
    components: Vec<SystemManifest>,
    wires: Vec<CrossWire>,
    marginal_compat: Option<CertFamRef>,
) -> Result<StochasticCouplingDecl, Refusal>
```

construction — `crates/mtk-catalogue/tests/compose_common/mod.rs`

```
let exo_block = {
    let m = MechanismBuilder::new()
        .interface(Interface {
            inputs: vec![],
            outputs: vec![wire(0, "w")],
        })
        .stochastic_wire(StochasticWire::Conditional {
            id: 0,
            sources: vec![],
            target: 0,
            rows: vec![
                CondRow {
                    given: vec![],
                    outcome: 0,
                    prob: r(1, 3),

)
.expect("fixture conforms to the stochastic-wire pattern")

```

## 13.9 Credal-Hull Certification

The two grades of open nondeterminism as one pattern. A system with unresolved choice — a policy slot, a scheduler slot — is certified either *at a declared resolution* (the resolution witness composed in; the closed object an ordinary citizen of the base frame's rows — the polling-automaton closure of section 12.15 is the landed instance) or *over the whole hull*: per-state-action row families asserting the generator inequality for *every* enabled choice, which covers deterministic, randomized (convexity — the rows are the simplex's extreme points), and history-dependent resolutions at once. The declared grade is the hull grade restricted to one vertex; the certified gap between them is real and priced (the demonic fixtures carry named breaking policies). Denotation: the credal lower expectation of the imprecise-semantics layer — and the semantics side of this pattern carries an adequacy receipt of its own: the demonic-face square of the decision-process section (section 12.13) mechanizes, at each finite horizon, that the compiled, policy-free presentation determines exactly the closed-loop law set over the memoryless randomized class, with the event-bound verdicts uniform over that class. **Witnessed**: a cliff-walk demonic pair (uniform bound with tightness witness), and the polling automaton's uniform re-certification, which thinned the declared grade's slack from  $5.13 \times 10^{-3}$  to eight parts per million without moving the bound.

## Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum's own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former's mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

$$\begin{array}{c}
\text{sys} : \text{SysRef} \quad m : \text{Mechanism the subject, } E(m) \neq \emptyset \\
\text{cert} : \text{CertFamRef} \quad \rho : \langle \text{state}, \text{action} \rangle, \text{ exactly one enabled action per open state} \\
\hline
\text{CredalHull}(\text{sys}; \text{cert}; \text{declared}(\rho)) : \text{CredalHullDecl} \quad \text{DECLARED}
\end{array}$$

$$\begin{array}{c}
\text{sys} : \text{SysRef} \quad m : \text{Mechanism the subject, } E(m) \neq \emptyset \\
\text{cert} : \text{CertFamRef} \quad h : \langle \text{state}, \text{action}, \text{driftBound} \rangle, \text{ exactly one row per pair of } E(m) \\
\hline
\text{CredalHull}(\text{sys}; \text{cert}; \text{quantified}(h)) : \text{CredalHullDecl} \quad \text{QUANTIFIED}
\end{array}$$

$E(m)$  is the subject's enabled choice set —  $\text{state} \mapsto \text{actions}$  read off its action-keyed outcome rows; a subject with no action-keyed structure is refused outright (no open choice — nothing for either grade to range over). The subject is consumed as formation data without appearing in the head form: it travels in the row by reference ( $\text{sys}$ ), and the coverage premises — one action per state for the vertex grade, since a partial resolution is not a vertex; one row per enabled pair for the hull grade, a gap's address serialized on refusal — are checked against the mechanism itself. Drift bounds are exact and sign-free (a supermartingale certificate's generator values are typically nonpositive); the generator-inequality *content* is the cited certificate family's business, recomputed at replay.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named  $\text{fx}_*$  or  $\text{f}.*$  are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript ---

The pattern-level TypeScript binding is not yet arranged: the manifest-level wiring descriptors (`WiringRow`, `SwitchEdge`, `ScheduleAssumption`) already ride the TS system namespace (`system.composite`), while the pattern builders and the four pattern row families are Rust-only at this preview.

### Rust `mtk_catalogue::compose::quantified_hull`

signature — `crates/mtk-catalogue/src/compose/credal.rs`

```
pub fn declared_resolution(
    sys: SysRef,
    subject: &Mechanism,
    cert: CertFamRef,
    rows: Vec<ResolutionRow>,
) -> Result<CredalHullDecl, Refusal>

pub fn quantified_hull(
    sys: SysRef,
    subject: &Mechanism,
    cert: CertFamRef,
    rows: Vec<HullRow>,
) -> Result<CredalHullDecl, Refusal>
```

construction — `crates/mtk-catalogue/tests/compose_common/mod.rs`

```
let big = WitRat::new(
    -"1234567890123456789012345678901234567890"
    .parse::<BigInt>()
    .unwrap(),
    BigInt::from(7u8),
);
quantified_hull(
```

```

SysRef("sys:cliffwalk-2".to_owned()),
&mdp_subject(),
CertFamRef("vfam:cliffwalk-lower".to_owned()),
vec![
  HullRow {
    state: 0,
    action: 0,
    drift_bound: r(-1, 8),
  },
  HullRow {
    state: 0,
    action: 1,
    drift_bound: big,
  },
  HullRow {
    state: 1,
    action: 0,
    drift_bound: r(0, 1),
  },
],
1,
)
.expect("fixture conforms to the quantified grade")

```

The declared grade (one vertex of the hull) is the corpus's `credal_declared_decl` sibling fixture.

## 13.10 Event-Port Patterns

A finished design whose primitive now carries a producer surface. Jump synchronization — two mechanisms' events declared to fire together — is constructible today: the toolkit's composite stratum stores typed fusion rows (capability legs across components' population edges, one firing law per event under the single-home discipline below), the pattern-level builder gates them, the coloured-net decomposition emits them, and the API block at the end of this section quotes the conformance constructions in both languages. Everything downstream of the primitive — resource pools, broadcast, dispatch, rate reasoning at fused boundaries — still speaks in design tense, settled to typing-rule depth (for the fusion core and resource pools, to certificate-transport depth) and recorded here so the remaining vocabulary lands on a fixed target; until it lands, synchronized structure beyond raw fusion lives inside single mechanisms, a granularity cost priced in the design's deferral note with its re-pricing trigger named.

### 13.10.1 Fusion

The primitive. Mechanisms expose selected transitions as *event ports* on their interfaces; a fusion row names a set of bound ports across a wiring, and the named transitions fire as one joint jump — a rendezvous rather than a broadcast [44]. Enabling is conjunctive over the parties' local guards, evaluated on the pre-jump composite state (snapshot semantics: each party reads the snapshot and writes only its own state, so resets within a fusion commute by construction). Every port carries a *modality*: at most one party in a fusion is *active* — the timing owner, whose transition kind (rate law, forced guard, or immediate) times the joint jump — while passive parties contribute enabling conjuncts and resets only, and never fire outside a fusion. The design's worked example is operator 1 of the Mini-Fab model (the standard five-machine semiconductor benchmark, chapter 17), who serves both lithography and implantation: “load starts” is one jump across station and operator — machine ready  $\wedge$  lot present  $\wedge$  operator idle — with the operator's idle  $\rightarrow$  task reset riding the same jump. The fusion row has landed on the producer side, with the decomposition feeding it: the toolkit's coloured-net decomposition (section 12.18) derives, for each transition, a fused event over the incident places' population edges — the legs as (component, edge) pairs, enabling arcs riding as read legs, the one firing law on the row — and emits it as the serialized fusion row the composite stratum stores and the pattern builder gates.

### 13.10.2 Resource Pools

A packaged pattern over fusion, not a new primitive: a shared resource is a pool mechanism (a counter  $k \in \{0, \dots, C\}$ , or a one-place coloured pool) with passive *take/give* ports, and a resource-share row family definitionally expands into that mechanism plus fusion rows binding each user's seize and release transitions.

A crossing discipline (each user declares which of its modes count as *holding* the resource; seizes enter the held set, releases leave it, no other transition crosses) makes the pattern’s payoff a theorem rather than a convention — the *conservation law*: for a well-formed pool share, every jump of the composite preserves

$$k_{\text{pool}} + \sum_{u \in \text{users}} \#H_u = C,$$

where  $\#H_u$  counts user  $u$ ’s units in held modes. The invariant is a count row [172], free by construction; raw fusion rows can express the same model and can also silently break the invariant — the packaged rows cannot, and that refusal is what the package is for.

### 13.10.3 Broadcast Fan-Out

One sender, many receivers. The inventory deliberately carries no broadcast primitive; it carries the *fixed-roster reduction*: when the receiver roster is finite and statically known — which is every use the catalogue’s source models have produced — a broadcast is a finite family of rendezvous fusions, and optional-join broadcast (each receiver participates only when locally enabled) is a finite family indexed by the participating subsets. Genuinely dynamic rosters are priced and deferred with the rest of the stratum.

### 13.10.4 Dispatch: Control Through Selection

Fusion creates contention: two fusions sharing a passive party conflict, and the enabled-conflict set is derivable from the fusion rows alone. Absent further data the conflict resolves demonically [13] — sound, and exactly as weak as it sounds. A dispatch row installs a policy: a chooser over the conflict set, reading current aggregate observables. Certificates are dispatch-indexed, with one free lemma (any dispatched policy refines the demonic envelope, so demonic safety transports to every policy) and one structural refusal (recurrence-class conclusions never cross an undischarged boundary). The design’s worked example is first-come-first-served against setup-affinity dispatch on the Mini-Fab model: two policies over an identical composite, with per-policy certified throughput the target — the setup-affinity policy’s advantage being exactly the kind of claim that is only ever *per-policy*, since the demonic envelope proves neither. Dispatch is the *per-epoch* member of the inventory’s control trio; its persistent sibling — control through enablement, where a supervisor carves the enabled set itself rather than selecting within it — is the supervision pattern (section 13.11), and the two compose because they are disjoint by kind.

### 13.10.5 Delayed Trace and the Delay Media

Feedback with memory: a delayed-trace row [223] closes a composite’s output back onto its input through a delay, well-defined precisely because the delay breaks instantaneous self-reference [53]. Delays themselves are first-class composition elements [154] in two species with a shared degenerate case — an event species (a one-place coloured-token place whose tokens carry a time-to-go coordinate) and a signal species (a transport medium: pure advection over the delay interval), both degenerating, when time is discrete and the delay is one step, to the *tick register*: the unit delay, which is also the minimal medium a delayed trace needs. The family exists so that delays compose like everything else — a delay is a mechanism with ports, not an annotation on a wire. For the signal species in continuous time, the semantics tier is already receipted: the delay-line adequacy square of the delay-differential-equations section (section 12.6) mechanizes exactly this composite — an ODE cell closed through the transport medium — so the pattern arrives with its continuous-time semantics a theorem and its producer surface landed: the delayed trace is a wiring, and the toolkit’s conformance corpus constructs the same composite — cell, line, and the two trace wires — through the composition surface (a dedicated delayed-trace row stays deliberately absent; the wiring is the pattern). The design’s flagship construction is the partially observable decision process: environment mechanism, observation channel, and a belief-tracking controller closed through a delayed trace — partial observability as a *composition* pattern rather than a new model class (section 12.14 grades the frame) — with the first certificate, a lower bound on achieved value for the classic two-door problem living on the belief simplex, already exercised in the workshop.

### 13.10.6 Event-Rate Assume/Guarantee

Rate reasoning across fused boundaries: an event-rate atom (the specification catalogue’s envelope pair, staged — section 14.6.4) bounds the firing rate of a shared event, a mechanism’s guarantee about its side of a fusion becomes its neighbour’s assumption, and assume/guarantee chains propagate rate bounds through a composite without unfolding it [28]. The delay place enters as a *rate-preserving element* — tokens are conserved, so the departure rate equals the arrival rate shifted by the delay, and a rate assumption crosses a delay medium unchanged. This is the pattern that would let throughput claims localize: bound the bottleneck’s service rate, and let rate-preservation carry the bound to the boundary where the specification states it.

## Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum’s own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former’s mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

*Producer-landed, theory-pending*: the fusion row family now has a builder underneath (the API block below quotes it), but no term former is stated ahead of its certificate-schema vocabulary — the formal block enters with the event-port interface stratum’s staging, and asserting a rule now, with no loader beneath it to refuse on its premises, would be exactly the invented formal block the first wing’s frontier entries refuse.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

The fusion primitive’s producer surface: a fusion row names capability legs (bag edges across a composite’s components, read legs included) that fire as one joint jump, with the event’s one firing law under the single-home discipline — exactly one active leg (its edge’s own law times the jump) xor a row-resident law over all-passive legs; both double-home and all-passive-lawless declarations refuse at build, along with leg resolution, membership (active-never-optional; a row-law fusion keeps a mandatory leg), and the delay basis (selection blocks per consuming/read leg, within-leg slot-exchange symmetry). The packaged patterns over fusion — resource pools, dispatch, event-rate atoms — remain design-tense and carry no API here.

**TypeScript** `compose.composite / system.composite (fusions)`

signature — `ts/src/system.ts`

```
/** S-EVENTPORT: one capability leg of a fused event — `edge` of
 * `components[component]`'s Bag self-loop roster. A leg whose edge
 * is `synced` is passive; an edge carrying its own local law is the
 * fusion's active leg (the timing owner). `membership` defaults to
 * `"mandatory"`; an `"optional"` leg joins only when locally enabled
 * (maximal join). */
export interface FusionLeg {
  readonly component: number;
  readonly edge: number;
  readonly membership?: "mandatory" | "optional";
}

/** S-EVENTPORT: the row-resident firing law of an all-passive fusion
 * — delay (rate per unordered selection across the consuming/read
 * legs' blocks, in leg order), guard (forced; every consuming/read
```

```

    * leg has delta 1), or immediate (the eager case, spelled
    * explicitly). */
export type FusionLaw =
  | { readonly kind: "delay"; readonly rate: Polynomial }
  | { readonly kind: "guard"; readonly guard: ReadonlyArray<DomainConstraint> }
  | { readonly kind: "immediate" };

/** S-EVENTPORT: one event-port fusion row – the named capability
 * legs fire as one joint jump (rendezvous), with the event's one
 * firing law under the single-home discipline: exactly one active
 * leg (`law` absent) xor all legs passive with `law` on the row. */
export interface FusionRow {
  readonly event: number;
  readonly legs: ReadonlyArray<FusionLeg>;
  readonly law?: FusionLaw;
}

```

construction — ts/tests/compose-native.test.ts

```

// The transfer rendezvous with an operator: a token leaves
// `upstream` and enters `downstream` as ONE joint jump, with an
// operator token read (never consumed). All legs are passive, so
// the law rides the row: a delay rate over the derived selection
// basis – the consumed token's colour, then the read operator's.
return compose.unwrap(
  compose.composite({
    name: "transfer-rendezvous",
    components: [
      bagStation(sys, "upstream", "destroy", 2),
      bagStation(sys, "downstream", "create", 1),
      bagStation(sys, "operators", "read", 1),
    ],
    fusions: [
      {
        event: 0,
        legs: [
          { component: 0, edge: 0 },
          { component: 1, edge: 0 },
          { component: 2, edge: 0 },
        ],
        law: { kind: "delay", rate: mono(2, 0, 1, "1/10") },
      },
    ],
  }),
);

```

bagStation and mono are the conformance corpus's shared fixtures, defined beside the quoted lines; the quoted construction's emitted bytes are the committed compose\_fusion golden vector, byte-identical across both language surfaces.

## Rust mtk\_catalogue::compose::CompositeBuilder::fuse

signature — crates/mtk-catalogue/src/system/compose.rs

```

/// System Catalogue: one event-port fusion row (`S-EVENTPORT`) – a
/// set of capability legs across the composite's components firing
/// as one joint jump (rendezvous, not broadcast), plus the event's
/// one firing law under the single-home discipline: either
/// exactly one leg is active (its edge's own law times the joint
/// jump; `law` absent) xor all legs are passive and `law` is
/// present on the row. Both double-home and all-passive-lawless
/// declarations refuse at [CompositeBuilder::build].
///
/// Enabling is conjunctive over the legs' local guards on the
/// pre-jump snapshot; each leg writes only its own component's
/// state (snapshot semantics, so reset commutation within a fusion
/// is a theorem – kernel-side, like every transport rule here).
///
/// [CompositeBuilder::build]: crate::compose::CompositeBuilder::build
#[derive(Debug, Clone, PartialEq, Serialize, Deserialize)]
pub struct FusionRow {
  /// Event id (roster-unique among the composite's fusion rows; for
  /// a decomposition image, the source SDCPN transition id).

```

```

    pub event: u32,
    /// The fused capability legs.
    pub legs: Vec<FusionLeg>,
    /// The row-resident firing law – present iff every leg is
    /// passive (the single-home XOR).
    #[serde(default, skip_serializing_if = "Option::is_none")]
    pub law: Option<FusionLaw>,
}

```

construction — crates/mtk-catalogue/tests/compose\_builders.rs

```

// The transfer rendezvous: a token leaves `a` and enters `b` as
// ONE joint jump. Both capability legs are passive (`Synced`
// edges), so the event's one firing law rides the row – a delay
// rate over the derived selection basis (the consumed token's
// colour coordinates).
let sys = CompositeBuilder::new()
    .component(bag_station("a", BagEdgeKind::Destroy, 2))
    .component(bag_station("b", BagEdgeKind::Create, 1))
    .fuse(FusionRow {
        event: 0,
        legs: vec![leg(0, 0), leg(1, 0)],
        law: Some(FusionLaw::Delay {
            rate: mono(1, 0, 1, r(1, 10)),
        }),
    })
    .build()
    .expect("legs resolve; all passive; law on the row");

```

`bag_station` and `mono` are the corpus's shared fixtures (tests/compose\_common); `FusionLeg`/`FusionLaw` and the membership column are declared beside the quoted row type, and the builder verb (`fuse`) runs the well-formedness gates at build.

## 13.11 Supervision: Control Through Enablement

Partially observed supervisory control [165, 206] over the coloured-net frame: a *supervisor* that can switch *some* declared plant transitions between enabled and disabled — not all of them, and never by firing them itself — that sees only declared observable functions of parts of the plant's marking, and that springs into action only when subscribed events occur. The entry's organizing fact is that the control seam costs nothing, because the inventory already carries it: **the gate is a place, and the gating is an enabling arc**. The policy is an ordinary jump-only System that owns places; a gated transition carries an ordinary weight-1 enabling arc (read-no-consume) from its gate place; enabling is minting the gate token and disabling is draining it — both ordinary jumps of the policy itself. No new arc kind, wire class, or row family exists for this pattern to add: enabling arcs are first-class in the coloured-net vocabulary at every stratum (section 12.18's arc table and the three faces of its adequacy development), and the inventory's seams for shaping a *live* component's behaviour thereby form a trio at three tempos — parameter setting (continuous, section 13.1), *enablement* (persistent, this entry), dispatch (per-epoch, section 13.10); the supervisory *edges* of mode switching (section 13.3) sit outside the trio, handing the active role between components rather than steering an active one. Gates carve the enabled set; dispatch selects within what survives; uncovered freedom stays demonic.

What the packaged row genuinely adds is bookkeeping with one new census clause. The package declares the ownership split — which places and which update transitions are the policy's — and derives the gated roster from it (every read arc sourced at a policy place; row-level, decidable, never separately declared). Its well-formedness census closes the information channels: policy inputs factor through the declared observables, subscriptions are the declared events, and — the clause the place-rendering itself demands — *arc separation*: plant transitions touch policy places through the declared gating read arcs only, with ordinary arcs refused in both directions (a plant transition producing into a gate place would be plant-side control of the policy's state), and policy updates carry no arcs on plant places at all — the policy acts on the plant through enablement, full stop. Raw rows remain lawful with the census as admission check, as for the inventory's other packaged rows. Zero-order hold between wakes is not even a lemma under this rendering: read arcs cannot move tokens, so no plant firing can touch a gate, and token presence has no drift to have. Gate places carry a Boolean discipline by default — capacity 1, gates as switches — and the discipline is deliberately omissible:  $k$  tokens in a gate place multiply a gated race's intensity by exactly

$k$  (the ordered census’s falling factorial at the gate place), so integer throttles come free by *not* imposing it, while fractional modulation remains parameter setting on rate content. The capacity declaration is accordingly a *must* wherever the model means Boolean gates: without it, an accidental second token silently doubles a rate.

The semantics per gated species is read off the landed faces rather than added to them. A gated delay transition is race thinning: gate closed, the ordered census vanishes (pre-enabling was always inside the count); gate open, the survivor law is the integrated-rate law, by memorylessness. A gated immediate transition is already inside the cascade square: gate coordinates are marking coordinates, so the tangible/vanishing classification, the scheduler discipline, and the cascade-rank certificate quantify over them unmodified — and the policy’s own wake is a cascade step like any other, so one structural rank discharges non-Zeno for every enabling-respecting scheduler, policy updates included. The whole pattern lives strictly inside the monotone fragment: disabling by *removing* a token is not a zero-test, enabledness stays upward closed (surplus gate tokens never disable a step), and the inhibitor exclusion is untouched — supervision is the monotone-safe rendering of control. Closure is on the nose: the supervised composite — plant places plus policy places, gating arcs, fused wakes — is again a coloured net of the same class, so supervision is composition *inside* the model class, and the fixed-policy adequacy statement is the net square applied to the supervised composite, no pattern-specific vertical. Mechanized at the uncoloured stratum (`SuFunctor.Adequacy.StochasticPetriSupervise`): the gating lemmas, the decidable arc-separation census with refusal witnesses in both directions, the Boolean-discipline preservation, and supervised micro-instances whose controls pin the closed, open, and graded race intensities as values, drive a two-step cascade *through* the policy’s own mint, and consume the landed cascade adequacy square at the supervised composite as an instance.

The pattern is a deliberate fourfold weakening of the probabilistic model checker’s scheduler — the adversary that tools in the PRISM and Storm family resolve [114, 148] — and each axis has a formal cash-out, landed or staged as the Status note records:

| axis          | scheduler (limit case)          | supervised variant                                                                                                                                                                                                            |
|---------------|---------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| control scope | resolves all nondeterminism     | read arcs on a declared roster; races stay stochastic, uncovered conflicts stay demonic — the controllable/uncontrollable partition is roster data                                                                            |
| effect        | the choice <i>is</i> the firing | the policy’s action type is its own marking: mint and drain in places it owns; the plant’s races and cascades do the firing — and the composite is again a net of the same class, where a scheduler lives outside its model   |
| observation   | reads full state                | reads declared observables of declared parts; measurability transposed into typing, checked at formation — adaptedness then a theorem about every well-formed composite, staged with the observation legs (Status note below) |
| activation    | consulted at every epoch        | wakes only at subscribed events; hold between wakes is read-no-consume; decision epochs are a declared sub-point-process of the plant’s event stream, non-Zeno by the shared rank certificate                                 |

Certificate polarity splits cleanly over the policy family, and the split is the entry’s payoff. *Safety is free across the whole family*: monotone enabledness makes refinement monotone in the gated roster, every well-formed policy’s closed-loop behaviour is contained in the demonic gate-envelope, so one safety certificate against the gate-demon transports to every partially observing policy — the information constraint costs nothing at this polarity. *Liveness over the unrestricted family is unprovable by construction*: the empty policy — no updates, gates never minted — is well-formed, so deliberate idling is expressible, and throughput claims are false over the family wherever a gated transition is load-bearing. That expressiveness is the commission, not a defect: deliberate idling is exactly the capability dispatch lacks (a chooser must choose; a supervisor may refuse), and it is why liveness certificates are per-policy here, exactly as they are per-dispatch in the previous entry, Kumar–Seidman teeth included [145]. The “some transitions, not all” clause has the same certificate-side reading: a total roster would make safety-under-supervision vacuous of plant content and

family liveness never provable; partial rosters keep both polarities informative.

One refusal survives, and it is the pattern's certificate-soundness story. At formation, gating is admitted on *every* transition species — including boundary-forced guard transitions, whose semantics stays total when disabled: a guard transition that is not pre-enabled imposes no forcing, and the run continues past its boundary untouched. What must not be gated, on pain of certificate unsoundness rather than semantic undefinedness, is a transition serving as a model's *box-discharge witness*: the certificate layer quantifies colours over compact rational boxes, the discharge obligation is what keeps the process inside the box the rows quantify over, and its default witness is itself an exit-guard transition. Gate that transition off and the process exits its box with positive probability while the certificate's rows still quantify over it. The obligation therefore lives at the certificate stratum, where the discharge already does: a gated transition may not serve as a box-discharge witness unless the model re-discharges by invariance or by stopped-process reading — a row-level lint on the package roster, decidable, and binding however the arcs were wired, because it is checked on the composite's rows rather than on any declared seam. On the semiconductor-fab model (chapter 17) the lint draws exactly the right line: a *suppressible deadline* is directly representable — gate an interior maintenance-window transition and the model means what it says — while the shift-boundary transitions are ungatable not because they are calendars but because they are their timer boxes' own discharge witnesses.

**Status:** the gating semantics and the arc-separation census are mechanized, sorry-free, at the uncoloured stratum (the module above, over the statics square and both dynamics faces), with refusal witnesses on every census clause and the graded-throttle identity pinned as a value; the coloured packaged row — observation legs as record-lens readouts, wakes as passive optional-join fusions — stages with the event-port interface stratum (section 13.10), and until it lands, supervised composites are hand-wired through the census door. The demonic gate-envelope face — the family-level object that safety certificates ride — is mechanized over the credal-hull machinery (section 13.9) at the uncoloured stratum: the certified policy seat is a dependent-index family (each member carrying its own termination rank — no automaton-level certificate can be uniform across the seat), its closed-loop laws inhabit one envelope on the common marking space, safety verdicts transport uniformly over the seat at both polarities, the envelope is monotone in the gated roster, and deliberate idling is a member — the mechanized face of the polarity split above.

## Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum's own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former's mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

*Former pending its strata; census landed.* The packaged row consumes an observation interface and a subscription list whose sorts stage with the event-port interface stratum (section 13.10), so no term former is asserted ahead of them — but unlike the entries that refuse their blocks outright, this pattern's one genuinely new formation premise already has a loader to refuse on it: the arc-separation census is a decidable row-level predicate, mechanized with refusal witnesses in both directions (a plant write into a gate place; a policy arc on a plant place). The gate map itself adds no premise sort at all — a gate is a weight-1 enabling arc from a policy-owned place, an arc kind every stratum of the coloured-net development already carries — and the ownership split is package data, invisible to the wire vocabulary.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit's conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus's shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

**TypeScript** ---

As for Rust: enters with the event-port interface stratum.

**Rust** ---

None yet, and the absence is a sequencing decision rather than a gap: supervision is a packaged pattern over fusion (event-triggered policy wakes) and enabling arcs (the gating), so its producer surface is sequenced behind the event-port interface stratum rather than built ahead of it. The pattern’s semantic tier is already mechanized in the toolkit’s Lean tree — the gating lemmas, the arc-separation census, and the supervised micro-instance with its cascade controls (module `SuFunctor.Adequacy.StochasticPetriSupervise`, over the statics square and both dynamics faces of the stochastic-Petri development) — so the builder, when it lands, arrives to a fixed semantic target.

## 13.12 State Sharing

The reserved axis: gluing along shared *state* — a jointly driven continuous variable, common noise — rather than signal wires. The designed semantics is the generator’s additivity over transitions sharing state,

$$\mathcal{A}_{\text{composite}} = \sum_i \mathcal{A}_i,$$

so certificates compose by summing generator contributions; the design warrant is recorded, and the axis is reserved rather than staged. Its first customers: common-noise mean-field composition, should that frontier entry of chapter 12 ever earn a producer surface, and the shared-place face of net composition — two nets glued along one common place — which is the one part of “nets of nets” that genuinely lives on this axis (the rest turned out not to need it; section 13.13).

### 13.12.1 Continuous State Sharing: Port-Hamiltonian Interconnection

The one pattern in the inventory’s design space that is not reducible to fusion: two mechanisms continuously driving one shared state have no events to synchronize — the content is drift superposition. The disciplined form is port-Hamiltonian interconnection: each mechanism carries an energy function and a power port (a paired effort/flow boundary variable), and composition couples ports power-conservingly, so the composite’s energy is the sum and energy-based certificates compose along the interconnection. The designed elimination has two species — additive, for flow-summed sharing, and an exact linear solve with a determinant-guard witness, for constraint coupling — and the guard is where the design pays for itself: the composite kinetic metric is a sum of pullbacks of positive-definite component inertias, so the division guards that must today be proven per model become structural consequences of the pattern. The design’s worked example is cartpole recomposed — cart and pole as separate Hamiltonian mechanisms coupled through a power-conserving pivot junction, recovering the standard monolithic dynamics as a theorem rather than an authoring choice. This design is in flight; this section records its intended shape.

## Computer Science Metanotation

as realized in the mechanized toolkit: the row vocabulary is the composite stratum’s own (`crates/mtk-catalogue/src/system/compose.rs` and the pattern row families of `crates/mtk-catalogue/src/compose/`), and the former’s mechanized ground truth is the builder signature quoted in the API block below, extracted at every regeneration. The formation rule, where the entry states one, is typeset by hand for notational quality, its premises the formation data the pattern builders consume and refuse on; transport soundness, tiering, and the causality/simultaneity side conditions are rule- and kernel-side, catalogued in the Rule Catalogue.

*Reserved:* no term former is stated ahead of the axis’s vocabulary. The design warrant — generator additivity, and the power-conserving junction rows of the port stratum — is recorded in the prose above, asserted as nothing until the axis stages.

## API

Producer surface of the mtk toolkit for this composition pattern: the TypeScript arrangement (npm package @maitria/mtk) and the Rust catalogue crate (crates/mtk-catalogue) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are extracted from the toolkit sources at every regeneration of this catalogue; each construction is quoted verbatim from the toolkit’s conformance corpus, code whose emitted certificate bytes are verified byte-identical against the committed golden vectors (helper values named `fx_*` or `f.*` are that corpus’s shared fixtures, defined beside the quoted lines). This API constructs and emits; it never checks — the checker re-derives every claim independently.

### TypeScript ---

As for Rust: reserved for a later revision of the producer surface.

### Rust ---

None by design at this preview: state-sharing / net-of-nets (gluing along shared state — places, common noise — rather than signal wires; the generator’s additivity over transitions as the designed semantics) is reserved for a later revision of the producer surface, with its design warrant recorded; SDCPN net-of-nets and common-noise mean-field composition are its first customers.

## 13.13 Nets of Nets

A closure property rather than a pattern, recorded as its own entry because the catalogue once reserved “nets of nets” as future vocabulary and most of the reservation dissolved under the term formers now stated. The population former is parametric in its inner System: S-BAG’s premise (section 12.17) is  $S : \text{System}$ , with nothing about  $S$  consulted beyond its sort. And the coloured-net former concludes at exactly that sort:  $\text{SDCPN}(P; T; A) : \text{System}$  (section 12.18). So a net whose tokens are themselves nets is one substitution — put a coloured-net System in the token-System slot where an ODE mechanism would ordinarily go, and the outer net’s places hold inner nets as tokens: hierarchy by instantiating a premise, not by any new row family. The base rung of the same ladder is already in the catalogue as the population entry’s identity anchor — a Bag of ODE tokens is the single-place, zero-arc coloured net, two presentations of one System — and each further rung is the same substitution one level up.

What this entry deliberately does not claim: the certification story across nesting depth. The well-formedness is free — that is the finding — but no shipped certificate yet exercises a population-of-nets carrier end to end, and the grading discipline of chapter 12 applies to the nested composite exactly as to any frame: depth adds obligations, not exemptions. What remains genuinely reserved is different in kind — two nets glued along a *shared place*, which is state sharing (section 13.12), not token colouring, and stays on that axis’s reservation.

No metanotation or API block: there is no former here to state — the entry’s formal content is two already-stated rules composing, and a dedicated block would only restate them.

# Specification Language

DRAFT

Every certificate in this stack ultimately concludes a claim of the form *this system satisfies this specification*. The Mathematical Models catalogue (chapter 12) is the normative inventory of the left-hand side of that judgment; this chapter is its right-hand side: the *spec language* — the temporal-logic proposition formers a modeller actually states requirements in — together with the record that packages a requirement for composition, the derived spellings that cover recurring claim species without new grammar, the rewrite layer that lets the *spec as stated* be the *spec as certified*, the deliberate absences, and the judgment kinds: the satisfaction-side sorts that certificates conclude into.

The presentation is semantics-first, and its form follows the rest of this book. The grammar is not given as productions: each former is a *deduction rule* in Computer Science Metanotation [225], concluding a formation judgment — premises above the line are the former’s well-formedness conditions, side conditions stand beside the rule, and what used to be checked into existence is now visible in the rule that brings the term into existence at all. The discipline pays twice. First, the deliberate absences of section 14.9 stop being policy prose: a fence is the *absence of a rule*, and several of the absences carry a semantic theorem as their warrant (section 14.2). Second, each formation rule is the natural index of its semantics: every former carries a *compile clause* into the spec storey of the semantic universe (chapter 9), an *adequacy obligation* relating the compile to the former’s intended reading — stated with its current status, machine-checked where it is machine-checked and named where it is owed — a *witness* from the certified corpus, and the producer *API* that constructs it. The record-level compile is a structural recursion over the formation derivation, so the adequacy of a whole specification is the fold of its rules’ cells (section 14.3).

**Why the grammar exists at all.** Before these formers were typed rows, two claim species — expected return and bounded always — lived in certificate-header *sidecars*: prose fields beside the proof rows, spelling claims the grammar could not. A claim that lives in a sidecar is a claim no checker re-derives and no composition rule can consume. The discipline this chapter enforces is the retirement of that disease: **a spec claim is a typed row**, and the rows’ schema has a normative home in this repository — theories/Qtsl.geolog, the theory encoding this chapter’s vocabulary as data, with its well-formedness and mutant battery beside it. Everything below exists so that the statement a reader sees is the statement the checker replayed.

The grammar is deliberately small — threshold atoms over observables, Boolean structure, probability, expectation, and level thresholds, run-functional accumulation, and the temporal operators (*always*, *always up to a deadline*, *reach by a deadline*, *until*, metered Streett acceptance) — and the catalogue’s completeness claim is empirical and checkable: **every claim species asserted by a certificate in the certified corpus appears in this chapter**, either as a former, as a derived spelling, or as a judgment kind — with the exercising artefact named. A claim species with no catalogue entry is a defect of the catalogue, never a licensed side channel: the admission rule is that a new species gets its former, with a named kernel and a named semantics obligation, when its first certificate lane arrives.

## 14.1 The Compile Target: Spec Classes of the Semantic Universe

What a specification denotes is fixed once, in the semantic universe, and this chapter compiles into it rather than re-deriving it. The stock this chapter consumes (chapter 9, section 9.7): a *spec atom* is a safety face together with a finite set of liveness demands; its class in the hyperspace is a *crescent* — one closed containment face cut by finitely many open escape faces, a locally closed set — and a compound specification in disjunctive normal form denotes the union of its disjuncts’ crescents, a *constructible* class.

Satisfaction is the fibre order itself: a system's belief (level-of-inconsistency functional; chapter 9) satisfies a spec when the spec's belief lies below it (`SuFunctor.Universe.Sat`), and the crisp judgment against a class has two faces — *safety* is wall domination, the system's permitted region contained in the demanded one, and *liveness* is a dip, some admitted state permitted at a finite level of inconsistency under each demand (`wallOn_le_iff`, `dip_top_iff`). Where the model leaves openness — demonic inputs, worst-case initial conditions, imprecise kernels — the judgment reads against a *set* of behavioural laws through the credal envelope faces (`SatCredal`, in the adequacy layer), lower for guarantees; a singleton set recovers the plain reading, a purely demonic model recovers min-over-branches. This one convention removes any need for separate worst-case formers.

An earlier edition of this chapter fixed four denotation strata — region, path, credal,  $\omega$ -word — as primitives of its front matter. They survive, but as *views* of the landed semantics, not as axioms of the catalogue:

- the *region* view: a state formula's denotation is a set of states, entering the judgment as threshold walls — and nothing expressible is lost by compiling regions to walls, because rational threshold rows generate the flat universe (`iSup_boxRows_eq_self`);
- the *path* view: a path formula's denotation is a class of records over the site — occupied-stage classes over the record lens at the finitary stratum, trajectory classes at the clocked strata (section 14.5);
- the *credal* view: probability and expectation atoms read *lower* bounds against the whole set of admitted laws, through the envelope faces named above;
- the  $\omega$ -word view: the rewrite layer (section 14.8) reads formulas over infinite words — one carrier instance among those a former admits, the one on which the eighteen rewrite rules are machine-checked today.

**The properness presupposition.** One structural fact of the compile target shapes the entire chapter, so it is stated once, here. Every spec atom's liveness set contains the top demand — in the mechanization this is a *field* of the atom (`SpecAtom.top_mem`), so an atom without it is not merely refused but unrepresentable — and therefore **every specification's interpretation includes the trivial liveness bound**: eventually *something*, at a finite level of inconsistency. Satisfaction of any spec asserts *safe and proper*: to satisfy anything, first exist. This is a law of the semantics, not a default a producer opts into — the compile emits the mark unconditionally, and that emission is itself a theorem (`eLabSpec_top_mem`) — and it costs nothing in syntax: there is no conjunct to write and no flag to store, because the demand lives in the judgment.

What it buys is that infeasibility is observable. An inconsistent system — one admitting no behaviour at all — satisfies every safety demand vacuously and no liveness demand (`top_notMem_modelClass`: the inconsistent system belongs to no spec class); a pure-safety reading would let a bricked system satisfy the specification of a working one, and composition could manufacture such systems from proper components while every certificate stayed green. Under the presupposition the true constant is not vacuous: `Spec(SInit(STtrue))` — the initial-state injection wrapping the true constant (section 14.3) — is the *bare feasibility spec*, the minimal claim distinguishing a bricked system from a working one (section 14.4.1). The same guard appears at the other end of the judgment, where the Rule Catalogue's liveness verdicts carry their existential conjunct (chapter 15) — one guard, two ends. What it costs is one nonemptiness discharge per root satisfaction claim, discharged where the claim is consumed; and where infeasibility is genuinely expected in some conditions, the honest spelling is the assumption slot of the spec record — satisfaction relativized to conforming inputs, with nothing demanded off-assumption (section 14.10.2) — never a properness opt-out, which the grammar deliberately does not provide.

## 14.2 Formation Judgments

Eight sorts carry the grammar, and they are not a flat list: four of them arrange as a two-by-two grid — the *temporal* axis (state: atemporal, against path: trajectory) crossed with the *shape* axis (observable:  $\mathbb{Q}$ -valued, against pred: Boolean) — and the grid is capped by the polarity sorts — two faces and the attitude blend — and the record.

|                   | Observable ( $\mathbb{Q}$ -valued) | Pred (Boolean)      |
|-------------------|------------------------------------|---------------------|
| State (atemporal) | $o$ StateObservable                | $\varphi$ StatePred |
| Path (trajectory) | $R$ PathObservable                 | $\psi$ PathPred     |

|                     |                                                           |
|---------------------|-----------------------------------------------------------|
| $o$ StateObservable | $o$ is a well-formed atemporal observable                 |
| $\varphi$ StatePred | $\varphi$ is a well-formed atemporal predicate (a region) |
| $R$ PathObservable  | $R$ is a well-formed run-functional                       |
| $\psi$ PathPred     | $\psi$ is a well-formed trajectory event                  |
| $\Phi$ ForallSpec   | $\Phi$ is a well-formed safety-face component             |
| $E$ ExistsSpec      | $E$ is a well-formed liveness-mark component              |
| $H$ AttitudeSpec    | $H$ is a well-formed attitude blend (a design score)      |
| $s$ Spec            | $s$ is a well-formed spec record                          |

Three of the eight are this edition's names for sorts the catalogue always had: StatePred was StateF, PathPred was PathF, and PathObservable was Return — repairing a standing defect of the earlier edition, whose formation table omitted Return entirely while eight rules concluded into it. StateObservable names the atemporal quantitative stratum that was previously anonymous: a polynomial argument, a channel index, a gate citation — material the rules always consumed without a judgment to its name; its four injections are now formers with an entry of their own (section 14.4.2). The two polarity caps are new, and they are the point of the redesign; the attitude cap completes them, entered with the theory revision because the blend it carries fits *neither* face — its discipline is stated at its entry (section 14.10.18). One further sort stands beside the eight as pair vocabulary rather than as a grid cell:  $\pi$  StreettPair ( $\pi$  is a well-formed request/response pair), feeding the two acceptance formers. Its dissolution into per-pair premise structure was designed, and the theory revision settled the question the other way, deliberately: the pair spine persists at the row stratum as list-spine *encoding* — small hash-consed nodes, pairs-as-data — with the two pair constructors carrying the consumption-parity vocabulary, and no rule reads the pair sort as a judgment.

**The stratification law.** The State row admits no trajectory quantification and no credal quantification; the Path row lifts State-row material along trajectories; **all quantification over the credal body happens at the cap, and the cap is where polarity lives.** A ForallSpec component reads its bound against *every* admitted law — the safety face, compiling to a floor: wall domination, the closed containment face of the compile target (section 14.1) — while an ExistsSpec component asserts that *some* admitted law attains — a liveness mark, compiling to a dip: the open escape face. An AttitudeSpec component reads *both* envelopes and mixes them arithmetically before thresholding — no face, no participation in the floor/mark algebra, a design score rather than a guarantee; in one line, **a Spec mixes verdicts; an attitude mixes envelopes** (section 14.10.18). Polarity is thereby a *sort*, not an annotation: a specification cannot be written without declaring the face of every component, a mis-faced premise is a formation error rather than a semantic surprise, and a rule that needs a face restriction states it as a sort premise instead of a prose side condition. The judgment layer is untouched — one turnstile, no subscripts: the face of every component is read off the constructor vocabulary of the *arguments*.

**The formers are the grid's structure maps.** Every former of this chapter lands on exactly one cell or arrow of the diagram:

- *within-cell structure* (State–Pred): the constants and Boolean closure — STRUE, SFALSE, SAND, SOR, SNOT;
- *within-cell structure* (State–Observable): the provenance injections oCHAN, oGATE, oPOLY (section 14.4.2) — one observable, whatever its provenance;
- *thresholding*, Observable  $\rightarrow$  Pred at the State row: SATOMLE, SATOMGE;
- *indicator embedding*, Pred  $\rightarrow$  Observable at the State row: oIND, the evident square-filler ( $1_\varphi$  as an observable);
- *temporal lifting*, Pred column, State  $\rightarrow$  Path: PALWAYS, PALWAYST, PDEADLINE, PUNTIL, the metered acceptance pair PDWELLSTREETT and PCROSSSTREETT, PNOTPATH;
- *accumulation*, Observable column, State  $\rightarrow$  Path: the accumulators poSUM, poINT, poDISC, poAVG, poSUP, each over one observable — the earlier edition's provenance-fused run-functional constructors, re-founded as injections plus accumulation modes at unchanged denotations — beside the transition-count functional RETFIRECOUNT (section 14.5.6);
- *indicator embedding*, Pred  $\rightarrow$  Observable at the Path row: RETPATH;

- *thresholding*, Observable  $\rightarrow$  Pred at the Path row: PATOMLE, PATOMGE — pathwise accumulated-cost events, a claim species distinct from any expectation bound (section 14.5.7);
- *the cap*: SPROBGE, SPROBLE, SRETURNGE, SRETURNLE, SLEVELGE, SLEVELLE, the event-rate envelope pair SRATEGE, SRATELE (over transition rosters, horizon-parametric — section 14.6.4), the initial-state injection SINIT, and the regret certificate face SREGRETLE conclude ForallSpec; the possibility marks SPROBMAYBEGE, SPROBMAYBELE, SRETURNMAYBEGE, SRETURNMAYBELE, SLEVELMAYBEGE, SLEVELMAYBELE, and the regret query face SREGRETLEMARK conclude ExistsSpec; the attitude pair SHURWICZGE, SHURWICZLE concludes AttitudeSpec. The mark roster is *polarity-total*: each threshold family — probability, expectation, level — presents both faces (the level marks are new with this edition, completing the grid), and the regret pair is the same duality one seat up (section 14.6.5);
- *the record*: Spec packages face components (section 14.3); and spec-level disjunction ( $s_1 \vee s_2$ ) Spec for  $s_1, s_2$  Spec — its denotation is the union of the two record classes, constructible by definition, and it never asks the impossible merge (the no-single-floor and no-single-mark facts below are about *one* record's slots); discharge is by disjunct selection.

**The one deliberate absence.** The completed diagram has exactly one missing arrow family, and it is absent on purpose: the *descending* arrows,  $\text{Path}\{\text{Pred}, \text{Observable}\} \rightarrow \text{State}\{\text{Pred}, \text{Observable}\}$  — nested path quantification in the CTL style, where a path-quantified claim re-enters the atemporal row as a state label ( $\mathbb{P}_{\geq q}[\psi]$  as a state predicate; a value functional as a state observable). Its status is recorded in three facts. First, the *raw* formers are not cautiously deferred but fenced by the geometry: a single level of such re-entry already exits the constructible classes — neither face's rooted class is a crescent — and the negation fence forbids recovering the universal face from the existential one, so any admission would have to carry both faces as primitives (the analysis is mechanized in the adequacy layer's path-to-state development). Second, the pathway is open, not closed: the behavioural tier already *denotes* the descending arrows — the probability-threshold and expected-return sets of the compile clauses below are exactly path-to-state denotations — and the principled admission route is a *certified-citation* former: the tower discipline promoted from convention to formation rule, Observable column first, where certified envelopes carry the right one-sided semicontinuity. Third, that route is deliberately out of scope for this edition, planned for the language's second major revision (2026Q4) — a choice made with the open pathway in full view, which is what distinguishes a scoped fence from an impossibility. What the certified corpus actually needs of nesting is already served through the judgment stratum: a child claim's *certified region* enters a parent formula as an ordinary StatePred atom (entry SPROBGE; the reach-then-hold spelling of section 14.7.2 is the landed witness).

**Refinements.** Two further judgments are read off derivations rather than declared:  $\varphi \Theta_0$  — membership in the *base stratum* (nonstrict polynomial atoms, constants, and their and/or closure; nothing else), demanded wherever a consumer needs base-exact material — and the *carrier-requirement synthesis*  $\psi \triangleright \kappa$  with  $\kappa \subseteq \{\text{steps}, \text{duration}\}$ , which computes what temporal structure a former demands of the carrier it is interpreted on (per-tick accumulation demands steps; deadlines, discounts, and time-integral accumulation demand duration). Under the grid the synthesis is a *Path-row device*, and the stratification law gains a checkable spelling: every State-row former synthesizes  $\triangleright \emptyset$  — atemporality as a computation, not a convention. Carrier scope is *derived, never stored* — the consequence for equivalence judgments is drawn at entry QSPEC EQUIV (section 14.10.5).

One further stratum is deliberately *not* a formation judgment: consumability at parity. Negation is a surface former (SNOT, PNOTPATH), resolved by negation normal form, and whether a residue survives to a consumable position is *checked* — by the producer-side typing preflight, and independently by the checker — not stored in the term. In rule form the refusal table becomes a family of absences: there is no rule concluding consumability of a negated path atom at even parity, of negated Streett acceptance, of negated bounded until, or of negated unbounded always. (The table's historical first member, the negated *probability* atom, no longer needs a row at all: no probability former concludes StatePred any more, so SNot cannot reach one — the fence became a type; the path atom of the theory revision inherits its seat in the table.) These absences carry a semantic warrant, stated once and cited by the fence entries: **under the properness presupposition, no spec class has an expressible complement**. The proof is two lines — every class excludes the inconsistent system (`top_notMem_modelClass`), so every complement *contains* it,

and no union of crescents does — so the class algebra is a distributive lattice, irreducibly non-Boolean, and the refused residues are not missing engineering but missing mathematics. The dual machinery that would consume them (probability upper bounds as positive claims, Rabin acceptance, over-approximating towers) is deliberately absent until a certificate lane demands it (section 14.9).

The surface grammar, its normal forms, and its compile are themselves mechanized, and the mechanization consumes the formation discipline literally: state predicates and path predicates are inductive types whose constructors are the rules below (`SuFunctor.Universe.SpecElab` and the path-lens development beside it) — and the mechanized state-predicate grammar was already atemporal and atom-abstract before the grid named the discipline, so `StatePred` is a rename at that stratum, not a rebuild; negation normal form has *no negation node by type*, so unconsumable residues have no clause because they have no constructor; and the compile is one clause per formation rule, with the record-level adequacy statement the fold of the per-rule cells over the formation derivation — the same architecture as the Rule Catalogue’s soundness, one lemma per rule composed by induction over admitted derivations, transposed from the inference stratum to the formation stratum.

**Sequencing.** The grid was enacted grammar-first, and this section is its normative statement; the normative theory’s row schema now carries it whole (`theories/Qtsl.geolog`): the re-sorted conclusions, the level marks, the initial-state injection, spec-level disjunction, the embedding and threshold arrows, the metered acceptance pair, the running-sup and transition-count functionals, the attitude cap, and the component-record assembly are all rows of the landed revision, with their well-formedness and mutant battery beside them. Denotations are unchanged throughout, and every inhabitant of the earlier edition’s grammar has a total spelling transport — the re-homed cap formers keep their names and field labels with only sort membership moved; a fused run-functional becomes its accumulator over the matching injection; a polynomial atom becomes the same atom over `oPoly`; a bare root region becomes its explicit `SINRT` component — so no certified artefact and no published number moved with the re-sort. The producer surface has since followed: the toolkit’s revision landed the grid spellings, and the quoted API blocks below are extracted from that revised surface — the residual producer gaps (the record-top disjunction, the compiled verdict form, the regret certificate face) are named at the entries that own them.

**How to read an entry.** Each entry carries two blocks. The *Formation* block states the former’s deduction rules, with  $\Theta_0$  rules inline where the former preserves or demands base membership and  $\triangleright$  annotations beside the rules that demand carrier structure. The prose beneath it states the *compile clause* — what the former elaborates to in the semantic universe’s vocabulary — the *adequacy* mode and status (exact where the compile’s class provably equals the intended reading; directed where a sound implication is proved and no converse is claimed; per consuming battery where the obligation is discharged rule-side), and the *witness*: the landed artefact that exercises the former.

The *API* block is the producer surface of the mtk toolkit for that entry: the TypeScript arrangement (npm package `@maitria/mtk`) and the Rust catalogue crate (`crates/mtk-catalogue`) — one Rust implementation underneath, reached from TypeScript in-process through a native binding, so the two surfaces cannot diverge. Signatures and constructions are quoted *verbatim* from the toolkit sources and its conformance corpus: code whose emitted certificate bytes are verified byte-identical against committed golden vectors, from both languages (the TypeScript-driven path re-emits the same bytes the Rust-driven path committed). The quoted blocks are regenerated mechanically from the sources by the catalogue’s extraction tooling — a missing declaration or marker fails the regeneration loudly — so quoted code cannot drift silently. This API constructs and emits; it never checks: constructors refuse malformed *syntax* with the failure’s geometry attached (which field, which subterm, which value), the typing preflight is a courtesy image of the checker-side oracle, and the checker’s independent replay is the only authority.

Two vocabulary facts used throughout, stated once. *Exact scalars*: every threshold, deadline, probability, and coefficient is an exact rational (0 in TypeScript, an exact-rational witness type in Rust); no floating point enters a claim. *Positional variables*: an atom’s polynomial reads the paired system’s state coordinates positionally — or, for interface-indexed specs, the interface’s output wires in list order (guarantees) and input wires (assumptions); port names are presentation data.

## 14.3 The Spec Record

### 14.3.1 Spec: root, interface, assumptions, slack

#### Formation

$$\begin{array}{c}
 \frac{\varphi \text{ StatePred}}{\text{SInit}(\varphi) \text{ ForallSpec}} \text{ SINIT} \\
 \\
 \frac{\Phi_i \text{ ForallSpec} \quad (i < m) \quad E_j \text{ ExistsSpec} \quad (j < k) \quad H_l \text{ AttitudeSpec} \quad (l < r) \quad \text{widths}(\vec{\Phi}; \vec{E}; \vec{H}) \text{ agree pairwise}}{\text{Spec}(\vec{\Phi}; \vec{E}; \vec{H}) \text{ Spec}} \text{ SPEC-C} \\
 \\
 \frac{\begin{array}{c} \Phi_i \text{ ForallSpec} \quad (i < m) \\ E_j \text{ ExistsSpec} \quad (j < k) \quad H_l \text{ AttitudeSpec} \quad (l < r) \quad \text{width}(\vec{\Phi}; \vec{E}; \vec{H}) = \text{arity}_{\text{out}}(I) \\ \alpha \text{ StatePred} \quad \alpha \Theta_0 \quad \text{width}(\alpha) = \text{arity}_{\text{in}}(I) \end{array}}{\text{Spec}(\vec{\Phi}; \vec{E}; \vec{H}, I, \alpha) \text{ Spec}} \text{ SPEC-I} \\
 \\
 \frac{s_1 \text{ Spec} \quad s_2 \text{ Spec}}{(s_1 \vee s_2) \text{ Spec}} \text{ SPEC-OR}
 \end{array}$$

A specification is a package of *face components* — alone (SPEC-C, the closed form) or against an interface with an optional  $\Theta_0$  assumption on input wires (SPEC-I); an optional slack slot (a candidate gain function for quantitative composition) may accompany either form. The rule shape wears the compile target's own algebra: the ForallSpec components conjoin invertibly — floors merge by pointwise maximum, one slot — while the ExistsSpec components aggregate as a *list*, because marks do not merge (no single mark expresses two demands; the record holds a list exactly where the semantics refuses a merge); the AttitudeSpec components stand beside the faced ones and render as design scores, never as guarantees (section 14.10.18), taking no part in either the floor merge or the mark list. A record must carry at least one component — across the three families, or a disjunction — as an admission conformance fact: the empty record claims nothing, and the bare feasibility spec is its minimal inhabitant. The initial-state injection SINIT is the honest name for what the earlier edition attached silently to a bare region at spec root: SInit( $\varphi$ ) reads *every admitted initial state satisfies  $\varphi$*  — the  $\forall$ -face reading, now one visible rule — so the bare feasibility spec is spelled Spec(SInit(STrue)), its properness mark carried by the judgment exactly as before (eLabSpec\_top\_mem unchanged). Spec-level disjunction (SPEC-OR) sits at the record top (section 14.2): a union of record classes, discharged by disjunct selection — deliberately *above* the record, so it never asks two records to merge into one floor slot and mark list; a disjunction record carries *no* component rows of its own (the exclusivity is refuse-mode at the row stratum: its class is its arms'), and or-graph acyclicity is admission conformance. Three record-level disciplines are rule shapes rather than checks. There is no rule introducing an assumption without an interface — “a spec carrying an assumption must carry an interface” is the absence of an  $\alpha$ -with-no- $I$  rule, and in the mechanization the assumption slot lives *inside* the interface option, so the discipline holds by type. Assumptions are policed to the base stratum at formation (temporal assumptions would reintroduce assume–guarantee circularity, so they are fenced at the grammar). And closed versus open is an absence distinction: a spec with no interface row is closed, and the closed satisfaction judgment is the empty-interface instance of the one satisfaction kind (entry QSAT) — there is no second sort for interface-indexed satisfaction, deliberately. The slack slot's  $\mathcal{K}_\infty$ -class membership obligations (zero at zero, monotone, unbounded) are discharged where the slack is *consumed* — by the composition rules of chapter 15 — never stored as facts. There is also deliberately *no model binding* on a spec: pairing a spec with its system is the satisfaction judgment's job, and a spec that named its model would be the sidcar disease in miniature.

At the row stratum the record reads the same way, at the row schema's grain. A specification is an *entity*; its face components attach as relation rows, one family per cap sort — spec\_forall, spec\_exists, spec\_score — zero or more rows each, read per the algebra above, with component presence, pairwise width agreement

(arity arithmetic), and the disjunction row’s exclusivity all admission conformance rather than rows. The earlier edition’s single root *attribute* is retired with the re-sort: a bare-region root was the `SINRT` conflation, and a mixed-face conjunction root is what the component families now spell explicitly. The interface and the slack (a declared candidate gain function — a polynomial, in the row schema) attach as zero-or-one relation rows; assumptions attach as *zero-or-more* relation rows, read conjunctively — several assumption rows constrain jointly, and each row is policed to the base stratum by a load-time refusal: a provably nonbase assumption is a malformed record, not a false one. The assumption-implies-interface discipline itself is carried by the formation calculus and the mechanization’s option type; the row schema leaves it to them.

*Compile.* The record-level compile is `elabSpec`: *interface resolution, then structural recursion*. Resolution fixes the record’s positional geometry — the interface’s arities for an open spec, pairwise width agreement for a closed one — and is total on conformant records (`resolveArity_isOk_iff`), refusing otherwise *before any recursion* with the failure’s geometry attached: the offending atom, its found width, the expected arity (`resolveArity_error_names_offender`). Decoded records re-validate with the same checks — decoded data is data. The recursion is then one clause per formation rule, and the compile factors through resolution (`elabSpec_isOk_iff`); its class-level adequacy is the fold of the per-former cells over the formation derivation (`elabSpec_ok_modelClass`), with the properness mark carried unconditionally (`elabSpec_top_mem`). One deferral, fail-closed and named: the compile reads the *guarantee* only. An assumption is carried as data — its conditional-satisfaction semantics (entry `QSAT`, the interface-indexed reading) is deferred, never silently read as an unconditional strengthening, and any consumer that would need it refuses until the relativized compile lands.

*Witness:* every certificate in the corpus pairs a system with a record of this shape; the interface-indexed form is exercised by the liveness vector quoted below (two output wires, one input wire, a  $\Theta_0$  assumption).

## API

The record-top disjunction (`SPEC-OR`) remains a logged deferred former on the producer side; everything else below is the revised all-relations surface.

**TypeScript** `spec.build / spec.encode / spec.init`

signature — `ts/src/spec.ts`

```
export interface Spec {
  readonly name?: string;
  readonly forall?: ReadonlyArray<ForallSpec>;
  readonly exists?: ReadonlyArray<ExistsSpec>;
  readonly score?: ReadonlyArray<AttitudeSpec>;
  readonly iface?: Iface;
  readonly assume?: StatePred;
  readonly slack?: Slack;
}

export function build(record: Spec): Result<Spec, SpecRefusal>

export function encode(record: Spec): Result<Artifact, SpecRefusal>

export function init(arg: StatePred): ForallSpec
```

construction — `ts/tests/spec-native.test.ts`

```
const art = s.unwrap(
  s.encode({
    name: "arbiter-liveness",
    forall: [recur0, recur1],
    iface: {
      invars: [{ name: "u", shape: [] }],
      outvars: [
        { name: "grant0", shape: [] },
        { name: "grant1", shape: [] },
      ],
    },
    assume: s.polyLe(1n, s.unwrap(s.polyVar(0, 1))),
  })
```

```

    }},
  );

```

The component families (SINIT + the forall / exists / score lists) are driven end to end by the formers-tour vector (the same test file).

**Rust** `mtk_catalogue::spec::Spec::builder`

signature — `crates/mtk-catalogue/src/spec/formula.rs + crates/mtk-catalogue/src/spec/record.rs`

```

pub fn builder() -> SpecBuilder

pub fn forall(mut self, f: ForallSpec) -> Self

pub fn exists(mut self, e: ExistsSpec) -> Self

pub fn score(mut self, h: AttitudeSpec) -> Self

pub fn build(self) -> Result<Spec, Refusal>

pub fn init(arg: StatePred) -> ForallSpec

```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```

let spec = Spec::builder()
    .forall(recur0)
    .forall(recur1)
    .name("arbiter-liveness")
    .iface(iface)
    .assume(assume)
    .build()
    .unwrap();

```

The component families (SINIT + the forall / exists / score lists) are driven end to end by the formers-tour vector (the same test file).

## 14.4 State-Row Formers

This wing is the grid's State row, whole (section 14.2): both cells and both arrows between them. State observables (StateObservable) carry the row's quantitative material — one observable, whatever its provenance — and state predicates (StatePred) denote *regions* — sets of states from which the claim holds — compiling to spec atoms whose safety face is the region's wall, with the properness mark on every atom; thresholding (SATOM) passes from observables to predicates, and indicator embedding (OIND) passes back. Everything here is atemporal by the stratification law, checkably: every former of this wing synthesizes  $\triangleright \emptyset$ . Trajectories enter with the next wing, and the credal body only at the spec faces (section 14.6). Two moves organize everything. The tower discipline of chapter 15 is *certificate-mediated*: a certified child region enters a parent formula as an ordinary StatePred atom through the judgment stratum, never by syntactic embedding (entry SPROBGE). And the grammar is closed, nonstrict, and canonical by construction, so the checker never normalizes — producers do.

### 14.4.1 STTrue and SFalse: the constants

#### Formation

$$\frac{}{\text{STTrue StatePred}} \text{STTrue} \quad \frac{}{\text{SFalse StatePred}} \text{SFalse} \quad \frac{}{\text{STTrue, SFalse } \Theta_0} \Theta_0$$

*Compile.* STTrue elaborates to the one-atom presentation  $(0, \{\top\})$  — the free wall carrying the properness mark alone — and SFalse to the empty disjunct family. Exact at the class level: the true constant's class is the proper systems (`SpecDnf.modelClass_top`), the false constant's class is empty (`SpecDnf.modelClass_bot`). Under the properness presupposition the true constant is therefore not vacuous: `Spec(SInit(STTrue))` is the

bare feasibility spec — the minimal claim distinguishing a bricked system from a working one — and certifying it is certifying existence.

*Witness*: exercised everywhere; `STrue` is the trivially-true base-exact Streett request under the recurrence sugar (entry `PDWELLSTREETT` and the derived spellings below).

## API

**TypeScript** `spec.TRUE / spec.FALSE`

signature — `ts/src/spec.ts`

```
export const TRUE: StatePred = Object.freeze({ kind: "true" as const });
/** `SFalse` — the empty set. */
export const FALSE: StatePred = Object.freeze({ kind: "false" as const });
```

construction — `ts/tests/spec-native.test.ts`

```
const orPart = s.or([s.FALSE, s.not(s.polyLe(0n, x1))]);
```

`TRUE` rides the formers-tour root (the grammar-tour vector of the same test file).

**Rust** `mtk_catalogue::spec::StatePred::{True, False}`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
/// `STrue` — the full space.
True,
/// `SFalse` — the empty set.
False,
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let or_part = StatePred::or(vec![
    StatePred::False,
    StatePred::not(StatePred::poly_le(q(0, 1), x1())),
]);
```

### 14.4.2 oChan, oGate, oPoly, oInd: the observable injections

#### Formation

$$\begin{array}{c}
 \frac{k \in \mathbb{N}}{\text{oChan}(k) \text{ StateObservable}} \text{oCHAN} \qquad \frac{g \text{ HypernetRef}}{\text{oGate}(g) \text{ StateObservable}} \text{oGATE} \\
 \frac{p \text{ Poly} \quad p \text{ canonical}}{\text{oPoly}(p) \text{ StateObservable}} \text{oPOLY} \qquad \frac{\varphi \text{ StatePred}}{\text{oInd}(\varphi) \text{ StateObservable}} \text{oIND}
 \end{array}$$

The State row's quantitative cell, and the stratum where reward *provenance* lives — so that everything downstream consumes *one observable, whatever its provenance*. A *channel* citation names a positional output wire of the paired subject's interface; channel-within-arity is record-level conformance at the pairing, where the interface is in hand, and the citation elaborates to the readout's gate there — computed, never trusted. A *gate* cites a scalar-codomain hypernet on the (possibly augmented) state carrier by content address — the carve vocabulary's gate object itself — with scalar-codomain-ness checked at admission, where the cited content is reachable; the demand is minted once, at the injection, and every gate-bearing consumer inherits it through this single locus. A *polynomial* is the view over the paired carrier's positional variables, carrying the canonicity premise (coefficients nonzero and exactly rational, exponent tuples of uniform width, strictly ascending in the canonical order — established by producer-side canonicalization rather than checked into existence). And `oIND` embeds a predicate as its characteristic observable ( $1_\varphi$ ) — the State row's `Pred` → `Observable` arrow, one of the grid's two indicator arrows (`RETPATH` is the other,

one per row): probability is the expectation of an indicator *by the diagram*, and the alias ties stay denotation lemmas at the mechanized stratum, never schema equations. Only the polynomial injection reaches the base stratum: a channel, gate, or indicator atom is nonbase by the refinement’s own negative rows, which is what keeps  $\Theta_0$  base-*exact* rather than base-shaped.

*Witness:* every polynomial atom in the corpus enters through oPOLY under the re-sort’s spelling transport; the channel and gate injections carry the provenance the run-functional formers of section 14.5.6 previously fused.

## API

**TypeScript** spec.oChan / oGate / oPoly / oInd

signature — ts/src/spec.ts

```
export function oChan(chan: number): StateObservable
export function oGate(digest: string, role?: string): StateObservable
export function oPoly(p: Poly): StateObservable
export function oInd(arg: StatePred): StateObservable
```

construction — ts/tests/spec-native.test.ts

```
const indAtom = s.atomGe(1n, s.oInd(band));
const chanObs = s.oChan(1);
```

**Rust** mtk\_catalogue::spec::StateObservable::{chan, gate, poly, ind}

signature — crates/mtk-catalogue/src/spec/formula.rs

```
pub fn chan(chan: u64) -> StateObservable
pub fn gate(gate: HypernetRef) -> StateObservable
pub fn poly(poly: Poly) -> StateObservable
pub fn ind(arg: StatePred) -> StateObservable
```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```
let ind_atom = StatePred::atom_ge(q(1, 1), StateObservable::ind(band.clone()));
let chan_obs = StateObservable::chan(1);
```

### 14.4.3 SAtomLE and SAtomGE: threshold atoms

#### Formation

$$\frac{c \in \mathbb{Q} \quad o \text{ StateObservable}}{\text{SAtomLE}(c, o) \text{ StatePred}} \text{ SATOMLE} \quad \frac{c \in \mathbb{Q} \quad o \text{ StateObservable}}{\text{SAtomGE}(c, o) \text{ StatePred}} \text{ SATOMGE}$$

$$\frac{c \in \mathbb{Q} \quad p \text{ Poly}}{\text{SAtomLE}(c, \text{oPoly}(p)), \text{SAtomGE}(c, \text{oPoly}(p)) \Theta_0} \Theta_0$$

The thresholding arrow of the grid: an atom bounds an *observable* against an exact rational, and the observable’s provenance is the previous entry’s business, not the atom’s. Over the polynomial injection this is the closed polynomial halfspace — the kernel’s native object, with no obligation standing between the atom and the exact arithmetic that checks it, and the only form the base stratum admits ( $\Theta_0$  reads the oPOLY image alone). Over a channel or gate injection the same atom thresholds the cited observable, its wall read at the pairing through the computed elaboration. The surface grammar is nonstrict *by construction*:

strict atoms are compiler-internal artifacts of negation normal form and are unrepresentable here — the schema’s testable negative; the negation of a closed atom is the strict open one, a normal-form-internal literal consumable at either parity (`den_compl_le`). Boolean wires need no dedicated former: “wire  $b$  is set” is spelled  $b \geq 1$  on a  $\{0, 1\}$ -valued wire (the derived spelling below cites the circuit suite, whose atoms compile to exactly this form).

*Compile.* The wall of the closed sublevel set, with the properness mark:  $\text{SAtomLE}(c, \text{oPoly}(p)) \mapsto (\text{wall}\{x : p(x) \leq c\}, \{\top\})$ , and symmetrically — channel and gate atoms compile the same wall species over the observable the pairing resolves. Exact: satisfaction of the compiled atom is containment of the permitted region in the halfspace *and* properness (`safetyAtom`, `coupledSat_safetyAtom_iff`, `safetyAtom_modelClass`), and nothing expressible is lost by compiling regions to threshold walls — rational threshold rows generate the flat universe (`iSup_boxRows_eq_self`), the generation theorem grounding the region view of section 14.1.

*Witness:* every certificate in the corpus.

## API

**TypeScript** `spec.atomLe / atomGe / polyLe / polyGe`

signature — `ts/src/spec.ts`

```
export function atomLe(c: QLike, o: StateObservable): StatePred
export function atomGe(c: QLike, o: StateObservable): StatePred
export function polyLe(c: QLike, p: Poly): StatePred
export function polyGe(c: QLike, p: Poly): StatePred
```

construction — `ts/tests/spec-native.test.ts`

```
const goal = s.polyGe(1n, s.unwrap(s.polyVar(0, 2)));
const cap = s.probGe(Q.of(3, 4), s.deadline(20n, goal));
```

`polyLe / polyGe` are the polynomial-atom conveniences (atom at the `oPoly` injection); polynomials are minted canonical by `poly / polyVar` (the same module).

**Rust** `mtk_catalogue::spec::StatePred::{atom_le, atom_ge}`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
pub fn atom_le(c: WitRat, o: StateObservable) -> StatePred
pub fn atom_ge(c: WitRat, o: StateObservable) -> StatePred
pub fn poly_le(c: WitRat, poly: Poly) -> StatePred
pub fn poly_ge(c: WitRat, poly: Poly) -> StatePred
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let goal = StatePred::poly_ge(q(1, 1), Poly::var(0, 2).unwrap());
let cap =
    ForallSpec::prob_ge(q(3, 4), PathPred::deadline(q(20, 1), goal, false).unwrap()).unwrap();
```

Polynomials are minted canonical by `Poly::new / Poly::var` (`crates/mtk-catalogue/src/spec/poly.rs`).

### 14.4.4 SAnd and SOr: Boolean structure

#### Formation

$$\frac{\varphi_i \text{ StatePred} \quad (i < n)}{\text{SAnd}(\varphi_0, \dots, \varphi_{n-1}) \text{ StatePred}} \text{SAND} \quad \frac{\varphi_i \text{ StatePred} \quad (i < n)}{\text{SOr}(\varphi_0, \dots, \varphi_{n-1}) \text{ StatePred}} \text{SOR} \quad \frac{\varphi_i \Theta_0 \quad (i < n)}{\text{SAnd}(\vec{\varphi}), \text{SOr}(\vec{\varphi}) \Theta_0} \Theta_0$$

$n$ -ary as built; binary presentations are sugar, folding through associativity of the exact cells.

*Compile.* Conjunction is the *atom merge*, disjunct-family-wise: safety floors join by pointwise maximum, mark families union — and the merge is exact, its class the intersection of the classes (`SpecAtom.modelClass_merge`, `SpecDnf.modelClass_conj`; the safety face is the conjunction-is-max universal property, the order-theoretic kin of `sat_sup_iff`). Disjunction is the disjunct union outright, and its class is the plain union (`SpecDnf.modelClass_disj`). Every merge carries the properness mark by construction. One design fact deserves its theorem here, because it is why the compile’s semantics is *class* semantics: disjunction of presentations is deliberately *not* the pointwise-minimum coproduct of beliefs. A proper system can hold its permitted region inside the union of two regions while belonging to neither disjunct’s class — models of a disjunction may *hedge*, and the presentation semantics excludes hedging; the gap is machine-checked (`exists_hedging_gap`), and the region reading collapses to safe-and-proper against the denoted region exactly on the disjunction-free fragment (`elabNnf_modelClass_disjFree`).

*Witness:* exercised everywhere; the full-grammar tour vector drives both constructors directly.

## API

### TypeScript `spec.and / spec.or`

signature — `ts/src/spec.ts`

```
export function and(args: ReadonlyArray<StatePred>): StatePred
export function or(args: ReadonlyArray<StatePred>): StatePred
```

construction — `ts/tests/spec-native.test.ts`

```
const orPart = s.or([s.FALSE, s.not(s.polyLe(0n, x1))]);
```

### Rust `mtk_catalogue::spec::StatePred::{and, or}`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
pub fn and(args: Vec<StatePred>) -> StatePred
pub fn or(args: Vec<StatePred>) -> StatePred
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let or_part = StatePred::or(vec![
    StatePred::False,
    StatePred::not(StatePred::poly_le(q(0, 1), x1())),
]);
```

## 14.4.5 SNot: negation under the closure discipline

### Formation

$$\frac{\varphi \text{ StatePred}}{\text{SNot } \varphi \text{ StatePred}} \text{ SNot}$$

Negation forms freely — and concludes nothing else: no rule puts a negation in the base stratum, and no compile clause consumes the residues that negation normal form cannot resolve.

*Compile.* By negation normal form. Negation is pushed to the leaves (De Morgan, double elimination), where a negated closed atom becomes its strict open literal; normal forms have no negation node *by type*, so the compile’s domain is a grammar in which unconsumable residues are unrepresentable, and what survives is compiled exactly — the resolution preserves the region semantics on the nose (`den_nnf`). The residues that do not survive — a negated path atom at even parity (the strict complement of an accumulated-cost event), negated Streett acceptance (Rabin), negated bounded until, negated unbounded always — are

absences of rules carrying the no-expressible-complement warrant of section 14.2: under the properness presupposition the class algebra has no complements to compile to. The producer-side typing preflight refuses each residue with a path address into the formula tree, and the unbounded-always refusal carries its remedy in the message: spell the intent as a producer-chosen deadline (PDEADLINE with the producerT flag).

*Witness:* the negation-duality suite and the rewrite layer’s normal forms; the preflight’s refusal geometry is test-pinned in both producer languages.

## API

### TypeScript spec.not

signature — ts/src/spec.ts

```
export function not(arg: StatePred): StatePred
export function preflightState(f: StatePred): Result<undefined, SpecRefusal>
```

construction — ts/tests/spec-native.test.ts

```
const orPart = s.or([s.FALSE, s.not(s.polyLe(0n, x1))]);
```

### Rust mtk\_catalogue::spec::StatePred::not

signature — crates/mtk-catalogue/src/spec/formula.rs + crates/mtk-catalogue/src/spec/typing.rs

```
pub fn not(arg: StatePred) -> StatePred
pub fn preflight_state_at(f: &StatePred, at: &FormulaPath) -> Result<(), Refusal>
```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```
let or_part = StatePred::or(vec![
    StatePred::False,
    StatePred::not(StatePred::poly_le(q(0, 1), x1())),
]);
```

## 14.5 Path-Row Formers

This wing is the grid’s Path row, whole (section 14.2): the temporal liftings that form trajectory events, the run-functional stratum that accumulates State-row observables along runs (PathObservable, entered after the liftings), and the row’s own thresholding arrow (PATOM) passing back from run-functionals to events. Path predicates (PathPred) denote sets of trajectories — *events*, and an event carries no face of its own: it enters a specification only through a cap former (the probability thresholds, or indicator accumulation via RETPATH into the prevision square), and the face — floor or mark — is declared by the consumer (section 14.6). One event, either face, and the sort says which is meant, every time. Their compile target is the *record* stratum of the semantic universe: at the finitary site, a path former reads the set of *occupied stages* of a record — and the site offers two readers of that set, the stage graph (the *touch* species) and the support of the occupation measure (the *dwell* species), with the record coupling condition saying exactly that the dwell reader is contained in the touch reader (recordCon\_iff\_stages). That one fact organizes the event formers’ semantics. Each former’s transport between the species is read off its *variance* in the occupied-stage set: invariance formers are antitone (a touch-certified claim transports to the dwell claim), reach formers are monotone (the transport flips), and the mixed formers — until, Streett — transport in *neither* direction, witnessed by explicit coupled separations (exists\_until0n\_species\_incomparable, exists\_streett0n\_species\_incomparable), so the absence of those transports is content, not omission. Polarity dictates the judgment face: invariance classes enter on the safety floor (the wall, and the landed record walls are the invariance compile’s floors — touchWall\_eq\_wall0n, dwellWall\_eq\_wall0n); reach classes enter on the liveness marks (mark0n, the mark twin of the wall), and the properness demand is the everything-goal instance of the localized liveness mark (mark0n\_univ): every “eventually” claim generalizes the bare existence claim by localizing its goal. The general record atom carries one safety class and one liveness class, and its satisfaction is *safe and proper-into-the-goal* (coupledSat\_pathAtom\_iff). At deterministic

records — the canonical lift of a stage graph — the two species coincide (`stages_uniformLift`) and the compile agrees with the trajectory clauses stated at each entry on the nose; the stochastic tier keeps only the directed transports. Windows at this stratum are natural numbers, for the same reason as the summed-return horizon: the finitary record site is tick-indexed and unitless; the duration-typed rational readings of the rules below keep their force at clocked continuum strata (validated-enclosure consumption), and the encoding question is the same one, unchanged.

### 14.5.1 PAlways: invariance

#### Formation

$$\frac{\varphi \text{ StatePred}}{\text{PAlways } \varphi \text{ PathPred}} \text{PALWAYS}$$

$G \varphi$ : the state formula holds at every time; no carrier requirement of its own.

*Compile.* The dwell class over the record site — records whose every occupied stage lies in the argument region (`alwaysOn`); trajectory clause  $\{\omega : \forall t. \omega(t) \in \llbracket \varphi \rrbracket\}$  at the deterministic cells. The class is closed (`isClosed_recordClass_always`), antitone in the occupied-stage set (touch certifies dwell), and enters the judgment as a safety floor. The safety battery consumes it (invariance and containment rows, chapter 15).

*Witness:* every avoid and invariance certificate in the corpus.

#### API

##### TypeScript `spec.always`

signature — `ts/src/spec.ts`

```
| export function always(arg: StatePred): PathPred
```

construction — `ts/tests/spec-native.test.ts`

```
| const alwaysPart = s.probGe(1n, s.always(band));
```

##### Rust `mtk_catalogue::spec::PathPred::always`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
| pub fn always(arg: StatePred) -> PathPred
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
| let always_part = ForallSpec::prob_ge(q(1, 1), PathPred::always(band.clone())).unwrap();
```

### 14.5.2 PAlwaysT: bounded always

#### Formation

$$\frac{T \in \mathbb{Q} \quad T > 0 \quad \varphi \text{ StatePred}}{\text{PAlwaysT}(T, \varphi) \text{ PathPred}} \text{PALWAYST}$$

$$\text{PAlwaysT}(T, \varphi) \triangleright \{\text{duration}\}$$

The state formula holds at every time up to the deadline — the claim shape of every validated-enclosure certificate (“the flow from the initial box stays in the tube over  $[0, T]$ ”), which is why the former exists: this catalogue holds that the spec as stated must be the spec certified, and this statement deserved a spelling.

*Compile.* The bounded dwell class: occupied stages within the window lie in the region (`windowAlwaysOn`; window a natural number at the tick-indexed stratum, per the wing preamble). The class is closed (`isClosed_recordClass_alwaysT`), antitone in the occupied-stage set and in the window — the window is an approximation source: a longer-window certificate consumes a shorter-window claim. Deterministic consumption is immediate (enclosure semantics is trajectory-wise); stochastic consumption at even parity awaits the over-approximating tower — the same fence as the probability upper bounds (section 14.9.3). Its normal-form dual *is* spellable: negated bounded always rewrites to bounded reach, so surface path negation over this former passes the preflight at both parities.

*Witness for the demand:* the enclosure fixture family (flow-tube certificates); the safety-until-deadline worked example; the LunarLander funnel holds.

## API

### TypeScript `spec.alwaysT`

signature — `ts/src/spec.ts`

```
| export function alwaysT(t: QLike, arg: StatePred): PathPred
```

construction — `ts/tests/spec-native.test.ts`

```
| const boundedPart = s.probGe(Q.of(1, 2), s.notPath(s.alwaysT(3n, band)));
```

### Rust `mtk_catalogue::spec::PathPred::always_t`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
| pub fn always_t(t: WitRat, arg: StatePred) -> Result<PathPred, Refusal>
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
| let bounded_part = ForallSpec::prob_ge(
|   q(1, 2),
|   PathPred::not_path(PathPred::always_t(q(3, 1), band.clone()).unwrap()),
| )
| .unwrap();
```

## 14.5.3 PDeadline: bounded reach

### Formation

$$\frac{T \in \mathbb{Q} \quad T > 0 \quad \varphi \text{ StatePred} \quad b \in \mathbb{B}}{\text{PDeadline}(T, \varphi, b) \text{ PathPred}} \text{PDEADLINE}$$

$$\text{PDeadline}(T, \varphi, b) \triangleright \{\text{duration}\}$$

The target region is reached by the deadline. The flag  $b$  (`producerT`) marks a producer-chosen horizon standing in for an unbounded reach — a sound under-approximation, carried *flagged* in the row so the reader of a certificate knows which kind of statement was made (the unbounded primitive is a deliberate absence; the derived spelling appears with the fences below).

*Compile.* The début (hitting) record class by the deadline: some occupied stage within the window lies in the target (`windowReachOn`); trajectory clause  $\{\omega : \exists t \leq T. \omega(t) \in \llbracket \varphi \rrbracket\}$  at the deterministic cells. The class is open (`isOpen_recordClass_deadline`), monotone in the occupied-stage set (dwell certifies touch —

the variance flip), and enters the judgment on the liveness face. Obligations: the deadline-battery kernels (geometric-decay and expectation-of-hitting arguments), machine-checked per the Rule Catalogue’s receipt columns.

*Witness:* reach-by-deadline certificates across the corpus; the certified-Gymnasium hitting waves (twenty-eight certificates of the quoted shape).

## API

### TypeScript `spec.deadline`

signature — `ts/src/spec.ts`

```
export function deadline(
  t: QLike,
  arg: StatePred,
  opts?: { producerT?: boolean },
): PathPred
```

construction — `ts/tests/spec-native.test.ts`

```
const goal = s.polyGe(1n, s.unwrap(s.polyVar(0, 2)));
const cap = s.probGe(Q.of(3, 4), s.deadline(20n, goal));
```

### Rust `mtk_catalogue::spec::PathPred::deadline`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
pub fn deadline(t: WitRat, arg: StatePred, producer_t: bool) -> Result<PathPred, Refusal>
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let goal = StatePred::poly_ge(q(1, 1), Poly::var(0, 2).unwrap());
let cap =
  ForallSpec::prob_ge(q(3, 4), PathPred::deadline(q(20, 1), goal, false).unwrap()).unwrap();
```

## 14.5.4 PUntil: safety until a deadline

### Formation

$$\frac{T \in \mathbb{Q} \quad T > 0 \quad \varphi_{\text{safe}} \text{ StatePred} \quad \varphi_{\text{tgt}} \text{ StatePred}}{\text{PUntil}(T, \varphi_{\text{safe}}, \varphi_{\text{tgt}}) \text{ PathPred}} \text{P}_{\text{UNTIL}}$$

$$\text{PUntil}(T, \cdot, \cdot) \triangleright \{\text{duration}\}$$

Stay safe until reaching the target, by the deadline; trajectory clause  $\{\omega : \exists t \leq T. \omega(t) \in \llbracket \varphi_{\text{tgt}} \rrbracket \wedge \forall s < t. \omega(s) \in \llbracket \varphi_{\text{safe}} \rrbracket\}$ .

*Compile.* The hitting-with-dwell record class (`until0n`): reach the target within the window, occupied stages strictly before staying safe. The mixed variance shows up everywhere the pure formers were simple: the class transports between the species in *neither* direction (witnessed, per the wing preamble), and its citizenship is the grammar’s first genuinely constructible-not-closed-not-open class — a finite union of locally closed pieces by window decomposition (`recordClass_untilF_eq`, `isConstructibleUnion_recordClass_untilF`), landing it squarely in the constructible stratum the compile target promises. The union-bound kernel that consumes it is machine-checked; negation of a bounded until has no sound compile target in this edition and is refused by the preflight with a path address.

*Witness:* the until-battery fixtures and the worked safety-until-deadline example.

## API

**TypeScript** `spec.until`signature — `ts/src/spec.ts`| `export function until(t: QLike, safe: StatePred, target: StatePred): PathPred`construction — `ts/tests/spec-native.test.ts`| `const untilPart = s.probGe(Q.of(9, 10), s.until(5n, band, s.polyGe(2n, x1)));`**Rust** `mtk_catalogue::spec::PathPred::until`signature — `crates/mtk-catalogue/src/spec/formula.rs`| `pub fn until(t: WitRat, safe: StatePred, target: StatePred) -> Result<PathPred, Refusal>`construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```

let until_part = ForallSpec::prob_ge(
  q(9, 10),
  PathPred::until(q(5, 1), band.clone(), StatePred::poly_ge(q(2, 1), x1())).unwrap(),
)
.unwrap();

```

**14.5.5 PDwellStreett and PCrossStreett: acceptance, metered****Formation**

$$\begin{array}{c}
\frac{\rho \text{ StatePred} \quad \rho \Theta_0 \quad \gamma \text{ StatePred}}{\text{PairBase}(\rho, \gamma) \text{ StreettPair}} \text{PAIRBASE} \quad \frac{\rho \text{ StatePred} \quad \gamma \text{ StatePred}}{\text{PairCmpl}(\rho, \gamma) \text{ StreettPair}} \text{PAIRCMPL} \\
\\
\frac{\pi_i \text{ StreettPair} \quad (i < n)}{\text{PDwellStreett}(\pi_0, \dots, \pi_{n-1}) \text{ PathPred}} \text{PDWELLSTREETT} \\
\\
\frac{\pi_i \text{ StreettPair} \quad (i < n)}{\text{PCrossStreett}(\pi_0, \dots, \pi_{n-1}) \text{ PathPred}} \text{PCROSSSTREETT}
\end{array}$$

Streett acceptance [226] — for each pair, an unbounded request forces an unbounded response — as *two* formers, because “unbounded” has two meterings and the record lens proves them incomparable: the mixed formers transport between the stage-graph reader and the occupation reader in neither direction, even on coupled points (the wing preamble’s witnessed separations). A metering flag would leave one former whose every consuming rule and citizenship theorem still cased on the flag with the type system enforcing nothing; two formers make the meter part of the *event’s identity* — the same move as the polarity redesign, one stratum down: metering as former, not annotation. PDwellStreett is occupation metering — unbounded request *occupation* forces unbounded response occupation (counting measure at tick strata, duration at clocked strata); you dwell on a street. PCrossStreett is entry-event counting — unboundedly many request *crossings* (fresh contact after absence, the countable, payable unit of touching) force unboundedly many response crossings; you cross a street. Enter-and-stay separates the species even at unit ticks — occupation diverges while the entry counter stops at one — and the two meterings at one pair list are distinct events, refuse-mode disjoint at the row stratum. Everything step-metered the catalogue already had is the dwell former’s unit-tick instance *by identity*: the liveness batteries, the acceptance event, and the recurrence sugar migrate there whole, and nothing migrates to the cross species, whose consuming machinery composes with the crossing-budget family at the behavioural tier. Where the species provably coincide — deterministic records, where the two stage readers agree — either former may be formed and the collapse theorem transports.

The pair vocabulary is metering-independent, shared verbatim. The two pair constructors are the two request-consumption modes — *parity as constructor choice, never stored data*: PairBase consumes the request base-exact, whence its  $\Theta_0$  premise (whose deliberate absence from PairCmpl is the point); PairCmpl

consumes the request through the syntactic complement’s over-approximation, stored positive. The recurrence and persistence operators are definitional instances, not formers:  $GF\varphi$  is a single dwell pair with a trivially-true base-exact request, and  $FG\varphi$  is the dwell pair whose complement-consumed request firing unboundedly forces the impossible response (both appear as derived spellings below). The face of an acceptance claim stays at the cap that consumes the event — two meterings by two faces, all four spelled compositionally. Negated Streett is Rabin acceptance — the dual judgment, a deliberate absence under either metering.

*Compile.* Two tiers, kept distinct. At the behavioural tier the dwell acceptance event lives on the kernel path measure, and the quantitative certificate bundle concluding it is machine-checked end to end (`sound_QStreettBundle`, composing into the probability-threshold region at entry `SProbGE`); the cross event’s infinitary reading is the entry-counter family, whose very definedness at continuum strata is the crossing-budget machinery’s evidence. At the record stratum the compile is the per-pair implication over occupied stages (`streettOn`), each former reading its *own* species — the dwell former the occupation support, the cross former the stage graph — as the *occupation shadow* of the infinitary acceptance condition, stated as such: a finite record has no “unboundedly often,” and the pasting between the record tier and the kernel path measure is deliberately not claimed here (it is the finite-dimensional-distributions stratum, the same fence the behavioural tier names). Both record classes are constructible; species transport fails in both directions, witnessed — which is the split’s warrant, restated as compile fact.

*Witness:* the 219-task liveness suite (specs normalized to  $\bigwedge_i GF\gamma_i$  — dwell spellings — and certified against circuit models); the cross former is new with the theory revision, its first certificate lane the crossing-budget composition.

## API

**TypeScript** `spec.dwellStreett / crossStreett / pairBase / pairCmpl`

signature — `ts/src/spec.ts`

```
export function dwellStreett(pairs: ReadonlyArray<StreettPair>): PathPred
export function crossStreett(pairs: ReadonlyArray<StreettPair>): PathPred
export function pairBase(req: StatePred, resp: StatePred): StreettPair
export function pairCmpl(req: StatePred, resp: StatePred): StreettPair
```

construction — `ts/tests/spec-native.test.ts`

```
const dwellPart = s.probGe(
  1n,
  s.dwellStreett([s.pairCmpl(band, s.polyGe(1n, x1))]),
);
const crossPart = s.proble(
  Q.of(1, 2),
  s.crossStreett([s.pairBase(band, s.polyGe(1n, x1))]),
);
```

A base-exact pair is also driven (through the recurrence spelling) by the liveness vector quoted under the derived spellings.

**Rust** `mtk_catalogue::spec::PathPred::{dwell_streett, cross_streett}`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
pub fn dwell_streett(pairs: Vec<StreettPair>) -> PathPred
pub fn cross_streett(pairs: Vec<StreettPair>) -> PathPred
pub fn base(req: StatePred, resp: StatePred) -> Result<StreettPair, Refusal>
pub fn cmpl(req: StatePred, resp: StatePred) -> StreettPair
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```

let dwell_part = ForallSpec::prob_ge(
  q(1, 1),
  PathPred::dwell_streett(vec![StreettPair::cml(
    band.clone(),
    StatePred::poly_ge(q(1, 1), x1()),
  )]),
)
.unwrap();
let cross_part = ForallSpec::prob_le(
  q(1, 2),
  PathPred::cross_streett(vec![StreettPair::base(
    band.clone(),
    StatePred::poly_ge(q(1, 1), x1()),
  )
.unwrap()]),
)
.unwrap();

```

### 14.5.6 The Return stratum

The Observable cell of the Path row: a PathObservable (the sort the earlier edition called Return) is a *run-functional* — what a run is worth, packaged as data — consumed by the expectation, level, and regret faces of section 14.6 and thresholded back into events by PATOM below. The cell is reached by accumulation from State-row material, and the theory spells it so: reward *provenance* (channel, gate, polynomial view, indicator) is the injection stratum of section 14.4.2, and *accumulation* is five formers over one observable — the earlier edition’s provenance-fused constructor roster (retChanSum through retAvg) re-founded as injections plus accumulators, at unchanged denotations. Beside the accumulators stand the two citation formers: RETPATH, the Path row’s indicator arrow, and RETFIRECOUNT, the transition-count functional.

### Formation

$$\begin{array}{c}
\frac{n \in \mathbb{N} \quad n \geq 1 \quad o \text{ StateObservable}}{\text{poSum}(n, o) \text{ PathObservable}} \text{poSUM} \quad \frac{T \in \mathbb{Q} \quad T > 0 \quad o \text{ StateObservable}}{\text{poInt}(T, o) \text{ PathObservable}} \text{poINT} \\
\\
\frac{\theta \in \mathbb{Q} \quad \theta > 0 \quad o \text{ StateObservable}}{\text{poDisc}(\theta, o) \text{ PathObservable}} \text{poDISC} \quad \frac{o \text{ StateObservable}}{\text{poAvg}(o) \text{ PathObservable}} \text{poAVG} \\
\\
\frac{o \text{ StateObservable}}{\text{poSup}(o) \text{ PathObservable}} \text{poSUP} \quad \frac{\psi \text{ PathPred}}{\text{retPath}(\psi) \text{ PathObservable}} \text{RETPATH} \\
\\
\frac{R \text{ TrList} \quad R \neq \text{nil}}{\text{retFireCount}(R) \text{ PathObservable}} \text{RETFIRECOUNT}
\end{array}$$

$$\text{poSum} \triangleright \text{steps} \quad \text{poInt} \triangleright \text{duration}$$

The two finite-horizon accumulators carry the integrality content the mechanization forced, now by *shape*: a discrete sum’s upper index is a natural number, and the tick-indexed strata that consume summed accumulation are unitless — no clock exists there against which a rational horizon could be rounded, which also rules out any rounding law at those strata (a system clock would make one spec denote different claims per clock). Integrated accumulation keeps its free positive rational horizon, which keeps its meaning at clocked continuum strata. The encoding decision the earlier edition left open is settled the strong way: split constructors with a natural-number tick horizon, so a rational tick horizon is unrepresentable rather than checked — and with the horizon split carried by the constructors, an integrality side condition has nothing left to check.

The remaining accumulators carry no horizon. poDisc is infinite-horizon exponential discounting at rate  $\theta$ : weights  $e^{-\theta t}$  on the internalized real-time base, under which tick systems embed at integer times

with weights  $e^{-\theta n}$  — kept exact in the log-rational grade, the same abstract-exponential discipline that keeps every transcendental out of the exact stratum. `poAvg` is the long-run average (the Cesàro limit); its certificate species is the gain/bias pair — a Poisson-equation drift row, the same supermartingale-shaped row grammar as everything above. `poSup(o)` is the pathwise running supremum of the observable along the run — horizon-free, read in the extended-real scale, where an infinite supremum makes an upper-bound claim *false*, never ill-formed. Its consuming shape is the maximal function: `SReturnLE(B, poSup(o))` bounds  $\mathbb{E}[\sup_t o(x_t)]$  over every admitted law, for which Doob’s maximal inequality is the natural certificate engine and the supermartingale row kit the natural feed — named with its species, its rule rows not yet claimed. Deliberately *not* minted beside it: a sup-outside-expectation former —  $\sup_t \mathbb{E}[\cdot]$  is a forall- $t$  family of marginal-law judgments, not a run-functional — and since  $\mathbb{E}[\sup] \geq \sup_t \mathbb{E}$  always, the per-instant-uniform reading arrives as a free corollary of the expressible, stronger form. `retPath( $\psi$ )` cites a path event as its indicator run-functional; temporal claims compile *into* this stratum (monitor automaton, product kernel, compiled state-reward gate, accumulation), following the value-functions-as-certificates route [3], under which the reward designs for Streett acceptance are state-valued indicators on the product carrier and the ordinary value function of a satisfying policy *is*, affinely, the certificate. The exact deadline table of chapter 15 is the value function of the compiled deadline reward — a reading, not a new obligation — and reinforcement learning becomes a sanctioned *producer* for the battery rows: powerful untrusted producers, small trustworthy checkers, as everywhere.

`retFireCount( $R$ )` is the transition-count functional: the total number of firings of the roster’s transitions along the run — no horizon, values in  $[0, \infty]$ , the same extended reading as the running supremum on its nonnegative fragment. The roster  $R$  is a positional list of transition citations of the paired subject; nonemptiness is formation (an empty roster would be the zero functional — a constant claim in count clothing, and canonical form forbids re-spelling), while duplicate-freedom and roster membership are pairing-relative demands at the certificate stratum, where the subject is in hand. Counting is firing-metered per roster member — deliberately *not* region-entry counting (that is PCROSSSTREETT’s device, section 14.5.5) and deliberately not the instant-crossing compensator mass of the Zeno seam: different species, not interchangeable. The consuming shape this former exists for is the hard count ceiling, `SReturnLE(B, retFireCount( $R$ ))` — along every admitted law, the total count of roster firings is at most  $B$  (section 14.7.7). The  $\geq$  face — at least  $n$  events, a genuine liveness claim consuming survival mass — is deliberately absent from this functional: that is throughput territory, and it enters at the expectation stratum rather than here — the event-rate envelope family’s lower face bounds the expected count from below, horizon-parametrically, over the same rosters (section 14.6.4).

## API

**TypeScript** `spec.poSum / poInt / poDisc / poAvg / poSup / retPath / retFireCount`

signature — `ts/src/spec.ts`

```
export function poSum(horizon: number, o: StateObservable): PathObservable
export function poInt(horizon: QLike, o: StateObservable): PathObservable
export function poDisc(o: StateObservable, rate: QLike): PathObservable
export function poAvg(o: StateObservable): PathObservable
export function poSup(o: StateObservable): PathObservable
export function retPath(arg: PathPred): PathObservable
export function retFireCount(trs: ReadonlyArray<number>): PathObservable
```

construction — `ts/tests/spec-native.test.ts`

```
const retLe = s.returnLe(100n, s.poInt(50n, s.oPoly(x0)));
const discFloor = s.returnGe(-5n, s.poDisc(chanObs, Q.of(1, 10)));
const countCeiling = s.returnLe(40n, s.retFireCount([0, 2]));
```

**Rust** `mtk_catalogue::spec::PathObservable::{sum, int, disc, avg, sup, path, fire_count}`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```

pub fn sum(horizon: u64, o: StateObservable) -> Result<PathObservable, Refusal>

pub fn int(horizon: WitRat, o: StateObservable) -> Result<PathObservable, Refusal>

pub fn disc(o: StateObservable, rate: WitRat) -> Result<PathObservable, Refusal>

pub fn avg(o: StateObservable) -> PathObservable

pub fn sup(o: StateObservable) -> PathObservable

pub fn path(arg: PathPred) -> PathObservable

pub fn fire_count(trs: Vec<u64>) -> Result<PathObservable, Refusal>

```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```

let ret_le = ForallSpec::return_le(
  q(100, 1),
  PathObservable::int(q(50, 1), StateObservable::poly(x0())).unwrap(),
);
let disc_floor =
  ForallSpec::return_ge(q(-5, 1), PathObservable::disc(chan_obs, q(1, 10)).unwrap());
let count_ceiling =
  ForallSpec::return_le(q(40, 1), PathObservable::fire_count(vec![0, 2]).unwrap());

```

### 14.5.7 PAtomLE and PAtomGE: accumulated-cost events

#### Formation

$$\frac{c \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{PAtomLE}(c, R) \text{ PathPred}} \text{PAtomLE} \quad \frac{c \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{PAtomGE}(c, R) \text{ PathPred}} \text{PAtomGE}$$

The thresholding arrow at the Path row — the grid’s admitted square-filler, entered with the theory revision: the *event* that the accumulated value lands on the stated side of the threshold, the inner clause of  $\mathbb{P}_{\geq p}[\sum r \leq B]$ . This is a claim species distinct from any expectation bound, and the distinction is the grid read column-wise: SReturnLE( $B, R$ ) bounds the *prevision* of  $R$  — one number per law, capped at the credal body — while PAtomLE( $B, R$ ) names the set of *runs* on which  $R$  lands under  $B$ , an event like any other, whose face is then declared by the cap that consumes it (a probability threshold, or indicator accumulation via RETPATH). Carrier requirements are inherited, not minted: the synthesis reads the run-functional argument ( $\text{PAtomLE}(c, R) \triangleright \kappa$  exactly when  $R \triangleright \kappa$ ).

*Compile.* Owed with the former’s first certificate lane — formation and the traversal stratum are landed at the theory revision; the record-stratum compile clause and its adequacy cell are named obligations, and no battery consumes the event yet.

*Witness for the demand:* the count-ceiling and budget families, whose probabilistic faces are exactly  $\mathbb{P}$ -thresholds over accumulated-cost events.

#### API

##### TypeScript spec.pathAtomLe / pathAtomGe

signature — ts/src/spec.ts

```

export function pathAtomLe(c: QLike, ret: PathObservable): PathPred

export function pathAtomGe(c: QLike, ret: PathObservable): PathPred

```

construction — ts/tests/spec-native.test.ts

```

const pathEvent = s.pathAtomGe(0n, s.retPath(s.always(indAtom)));
const eventCap = s.probGe(Q.of(3, 4), pathEvent);

```

**Rust** `mtk_catalogue::spec::PathPred::{atom_le, atom_ge}`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
pub fn atom_le(c: WitRat, ret: PathObservable) -> PathPred
pub fn atom_ge(c: WitRat, ret: PathObservable) -> PathPred
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let path_event = PathPred::atom_ge(
  q(0, 1),
  PathObservable::path(PathPred::always(ind_atom.clone())),
);
let event_cap = ForallSpec::prob_ge(q(3, 4), path_event).unwrap();
```

## 14.5.8 PNotPath: surface path negation

### Formation

$$\frac{\psi \text{ PathPred}}{\text{PNotPath } \psi \text{ PathPred}} \text{ PNotPath}$$

Surface-only path negation, resolved by the dualities in negation normal form.

*Compile.* By the normal-form dualities — and the fence table is *executable*: normal-form resolution is a total function into either a negation-free form or a named refusal, and each row of the table is a definitional equation. The one always-spellable dual resolves at both parities — negated bounded always is bounded reach of the complement (`pathNnf_notPath_alwaysT`), and the even parity of a bounded reach resolves through double negation (`pathNnf_notPath_notPath_deadLine`) — while the three residues refuse with their addresses: negated unbounded always, negated until, negated Streett (`pathNnf_notPath_always`, `pathNnf_notPath_untilF`, `pathNnf_notPath_streett`). The path-atom formers of the theory revision extend the refusal roster at the producer surface: a negated path atom at even parity is the strict complement of an accumulated-cost event — a normal-form artifact with no surface spelling — refused with the same path-address geometry, as a documented extension of the pinned oracle. One note on the warrants, because they differ by stratum: at the record-class level the complement of an invariance class *does* exist (`not_alwaysOn_iff` — some occupied stage escapes), so the refusal of negated unbounded always is grammar economy — there is no unbounded-reach former to spell the dual, itself a deliberate absence — whereas at the spec-class stratum one level up, where the judgment kinds live, the refusals carry the no-expressible-complement theorem of section 14.2.

*Witness:* the negation-duality suite; the full-grammar tour vector’s `PNotPath( $G_{\leq 3} \varphi$ )` passes the preflight at both parities.

### API

**TypeScript** `spec.notPath`

signature — `ts/src/spec.ts`

## 14.6 Spec-Face Formers

The wing above the grid. Every former here consumes run-valued material — an event, a run-functional, or (for the rate envelopes) a transition roster read as a horizon-parametric counting process — reads it against the credal body, and concludes into a polarity cap sort, so this wing is where a claim first acquires a *face*: the stratification law of section 14.2 puts all quantification over admitted laws here and nowhere else. Formers concluding ForallSpec are the safety faces — the bound holds over *every* admitted law, compiling to the floor — and the Maybe and Mark formers conclude ExistsSpec, the possibility faces: *some* admitted law (or, for regret, some filler) attains, compiling to a mark. The roster is polarity-total — probability, expectation, and level each present both faces, and the regret pair is the same duality with the quantifier moved to the filler seat. Two cap formers live with their consumers instead of here: the initial-state injection SINIT, stated with the record it feeds (section 14.3), and the attitude pair, which mixes envelopes rather than declaring a face and closes the judgment-kind inventory (section 14.10.18).

### 14.6.1 SProbGE, SProbLE, and the probability marks

#### Formation

$$\frac{p \in \mathbb{Q} \quad 0 < p \leq 1 \quad \psi \text{ PathPred}}{\text{SProbGE}(p, \psi) \text{ ForallSpec}} \text{ SProbGE} \quad \frac{q \in \mathbb{Q} \quad 0 \leq q < 1 \quad \psi \text{ PathPred}}{\text{SProbLE}(q, \psi) \text{ ForallSpec}} \text{ SProbLE}$$

$$\frac{p \in \mathbb{Q} \quad 0 < p \leq 1 \quad \psi \text{ PathPred}}{\text{SProbMayBeGE}(p, \psi) \text{ ExistsSpec}} \text{ SProbMayBeGE}$$

$$\frac{q \in \mathbb{Q} \quad 0 \leq q < 1 \quad \psi \text{ PathPred}}{\text{SProbMayBeLE}(q, \psi) \text{ ExistsSpec}} \text{ SProbMayBeLE}$$

One species, four faces. SProbGE( $p, \psi$ ) — historically this stack’s only probability former, under the name SProb — asserts that the path event holds with probability at least  $p$ , read as *lower* probability against the credal view, over every admitted law — whence its ForallSpec sort; the initial-state datum enters the satisfaction judgment in hypothesis position, not the formula — so one convention serves stochastic kernels, demonic branching, and worst-case initial conditions without a case split. SProbLE( $q, \psi$ ) is the second orientation *within* the species, not a mirror species: the *upper* probability of the same compiled event is at most  $q$ . It is a closed constraint whose wall is a citizen of the semantic universe like any other, and emphatically *not* the negation of the GE face — that is the strict  $P_{<p}$ , which rightly remains a compiler artifact (the fences below keep that absence). The Maybe pair carries the *possibility marks*: some admitted law attains the stated side of the threshold — the credal-existential face of the atom, a liveness demand entering on the marks rather than the floor.

What the earlier edition advertised as nesting is stated, under the grid, at its true stratum: the tower discipline is *certificate-mediated*. A child claim is discharged as its own satisfaction judgment, and its *certified region* enters the parent formula as an ordinary StatePred atom — geometry with a certificate behind it, not a formula inside a formula. Syntactic nesting of cap formers (a probability atom inside another’s path argument) is not formable — Path-row formers take StatePred arguments — and the certified corpus never spelled such a term: its one advertised nesting use, the reach-then-hold funnel, already routes the child claim through the judgment stratum (section 14.7.2 quotes it). The grammar now matches what the tower always did.

The family is a family of *aliases*: an event probability is the expectation of an indicator gamble, so orientation for orientation

$$\text{SProbGE}(p, \psi) = \text{SReturnGE}(p, \text{retPath } \psi),$$

and likewise for the LE face and both marks (section 14.6.2). The alias ties are definitional-grade denotation lemmas at the mechanized stratum, never schema equations: the surface constructors remain distinct hash-consed syntax, and the elaboration is computed where consumed.

The interval premises are *canonicity rules, not semantic fences* — four instances of one rule: the vacuous end of either orientation re-spells a structural part of the atom, and canonical form forbids re-spelling. At  $p = 0$  the GE floor (and at  $q = 1$  the LE floor) would compile to the unit atom, which is exactly `STrue`’s compile (`SpecDnf.modelClass_top`); at  $p = 0$  the `MayBeGE` mark reads “some admitted law with  $\mu(\psi) \geq 0$ ” — the structural properness mark itself (`SpecAtom.top_mem`), as does the `MayBeLE` mark at  $q = 1$ . Bottom-refutes was never carried by threshold positivity: the credal-lower reading is vacuous at the zero lift for every constraint (`satCredal_lower_singletonC_zero`), and it is the properness presupposition that excludes the bricked system.

*Compile.* The GE face: the region of states from which the credal-lower probability of the compiled path event clears the threshold — mechanized for the kernel path measure as `probThresholdSet`, entering the judgment as that region’s safety atom. Adequacy is *directed*: region inclusion transports to class inclusion (`safetyAtom_modelClass_mono`, the wing’s directed-cell template; `sprobAtom_modelClass_mono`), and each consuming battery discharges the sound direction — the Ville [234] and optional-stopping arguments behind the safety, deadline, until, and Streett batteries of chapter 15, per that catalogue’s receipt columns. One end-to-end specimen is machine-checked at the behavioural tier: a quantitative Streett certificate bundle concludes membership in the probability-threshold region of the acceptance event (`sprob_sound_of_streettBundle`). No completeness is claimed anywhere in this family: a certificate can be arbitrarily loose. The LE face enters as the same wall species at the opposite orientation — the checker-anchor restriction theorem already lists *both* threshold orientations as closed half-spaces of laws, and the negation-fence remark names the orientation pair the sound residue of the failed duality. The marks enter on the atom’s mark list — the mechanized `Dip`: a strict undercut somewhere admitted. Formation is open on all four faces; *consumption* of the LE face at interior  $q$  keeps its over-approximating-tower fence (section 14.9.2), while  $q = 0$  discharges on the exact lane today: an exact backward-induction table is simultaneously an under- and over-approximation, so the possibilistic prohibition  $\bar{P}[\psi] = 0$  — the semantic universe’s own behavioural-prohibition face — is certified by the same table read in the super-solution direction. Two compatibility facts anchor the credal reading at the precise end: at the singleton lift of a nonzero law, the lower reading of an event atom is that law’s own event probability (`satCredal_lower_singletonC_gec`); and the zero-lift vacuity above.

*Witness:* the supermartingale corpus end to end; the reach-by-deadline vector quoted below is the certified-Gymnasium hitting shape ( $\mathbb{P}[\text{goal by } 20] \geq 3/4$ ); the exact-zero avoidance claims of the deterministic corpus spell natively on the LE face.

## API

```

The MAYBE marks construct in the marks vector quoted under the seat-regret entry (the same test file).

## 14.6.2 SReturnGE, SReturnLE, and the possibility marks

### Formation

$$\frac{B \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{SReturnGE}(B, R) \text{ ForallSpec}} \text{SRETURNGE} \quad \frac{B \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{SReturnLE}(B, R) \text{ ForallSpec}} \text{SRETURNLE}$$

$$\frac{B \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{SReturnMayBeGE}(B, R) \text{ ExistsSpec}} \text{SRETURNMAYBEGE}$$

$$\frac{B \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{SReturnMayBeLE}(B, R) \text{ ExistsSpec}} \text{SRETURNMAYBELE}$$

The *soft* former: the prevision square at a run-functional. The floors read the paired System’s credal body at the gamble  $R$  — credal-lower expectation at least  $B$  (GE), credal-upper expectation at most  $B$  (LE) — and the marks are the credal-existential faces: some admitted law attains the stated side. Nothing on the spec side carries a set of models: under the one-universe reading the System’s own denotation is the weighted set, and the spec carries only the pair  $(R, B)$ . This is where minimax weighted expected regret lands without new vocabulary: a weighted set of probability measures [108] is, member for member, a set of sub-probability laws ( $\alpha \text{Pr}$  for weight  $\alpha$ ), i.e. a credal body in this universe’s own imprecise atlas; the sup-normalization convention (some member carries weight one) is the properness presupposition; and the weighted expected regret of a nonnegative run-functional is the body’s upper prevision. “WER within  $[B_1, B_2]$ ” is therefore the two-component record  $\text{Spec}(\text{SReturnLE}(B_2, R); \text{SReturnMayBeGE}(B_1, R))$  — one floor, one mark, the same denotation the earlier edition spelled as a state-level conjunction, with the face of each component now visible in its sort; no interval sort exists: ranges are orientation pairs here as everywhere in this catalogue. Bounds are unconstrained rationals — returns are not probabilities, and the vacuous-end canonicity rule is a probability-face fact.

*Compile.* Credal-lower/upper expectation rows over the declared reward, lifted at the measurable stratum; the finite-horizon summed channel form is mechanized as `returnGESet` (natural-number horizon, as the split now forces by shape), entering the judgment as that region’s safety atom, with region monotonicity in reward, horizon, and bound as the directed cells (`returnGESet_mono_reward`, `returnGEAtom_modelClass_mono_reward`). Adequacy is *directed*, certificate to claim, and the two square families carrying it are machine-checked at the abstract behavioural tier: a geometrically decaying Lyapunov certificate — drift factor  $\beta$  off the target, barrier  $a$  — yields the expected indicator-return bound  $1 - \beta^n (\int L_0)/a$  at horizon  $n+1$  (`returnGE_sound_of_deadline`); and a geometric-drift certificate bounds the discounted expected return from above, uniformly in the horizon, under the spectral condition  $\gamma\beta < 1$

(discountedReturn\_le\_of\_drift, with integral\_le\_pow\_mul the iterated-drift engine). Both squares are proved on an abstract filtered probability space, where the certificate’s conditional-drift data lives; the specialization to the kernel path measure is a separate, named stratum — an obligation this edition names rather than claims — and the transfer from the deadline kernel to the discounted return forms climbs the same ladder. The marks enter on the atom’s mark list (Dip), exactly as the probability marks do; the long-run-average battery (gain/bias) is design vocabulary of this edition, named with its species and not yet claimed. This family is the catalogue’s highest-priority former because of what it retired: until it existed, expected-return certificates carried their claims in header sidecars.

*Witness for the demand:* twenty-five tabular expected-return certificates ( $\mathbb{E}_\pi[\sum r] \geq B$  — Cliff Walking —13 exactly; Taxi 793/100; Blackjack —3954908734551683826282634489/13<sup>26</sup>, the corpus’s own bignum, quoted below); the pendulum swing-up worst-case return row ( $\geq -619.99$  from every default-reset initial state); the Atari circuit rows (min-over-lanes return, exact); the LunarLander statistical rows (via QSATCONF below).

## API

**TypeScript** spec.returnGe / returnLe / returnMayBeGe / returnMayBeLe

signature — ts/src/spec.ts

```
export function returnGe(lo: QLike, ret: PathObservable): ForallSpec
export function returnLe(hi: QLike, ret: PathObservable): ForallSpec
export function returnMayBeGe(lo: QLike, ret: PathObservable): ExistsSpec
export function returnMayBeLe(hi: QLike, ret: PathObservable): ExistsSpec
```

construction — ts/tests/spec-native.test.ts

```
const ret = s.poSum(26, s.oChan(0));
const floor = s.returnGe(
  Q.of(-3954908734551683826282634489n, 13n ** 26n),
  ret,
);
```

The accumulator injections are quoted under the Return stratum; the poInt / poDisc faces and the possibility marks ride the formers-tour vector (the same test file).

**Rust** mtk\_catalogue::spec::ForallSpec::{return\_ge, return\_le}

signature — crates/mtk-catalogue/src/spec/formula.rs

```
pub fn return_ge(lo: WitRat, ret: PathObservable) -> ForallSpec
pub fn return_le(hi: WitRat, ret: PathObservable) -> ForallSpec
pub fn return_may_be_ge(lo: WitRat, ret: PathObservable) -> ExistsSpec
pub fn return_may_be_le(hi: WitRat, ret: PathObservable) -> ExistsSpec
```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```
let thirteen_pow_26 = (0..26).fold(BigInt::from(1), |a, _| a * 13);
let bound = WitRat::new(
  BigInt::parse_bytes(b"-3954908734551683826282634489", 10).unwrap(),
  thirteen_pow_26,
);
let ret = PathObservable::sum(26, StateObservable::chan(0)).unwrap();
let floor = ForallSpec::return_ge(bound, ret);
```

The accumulator injections are quoted under the Return stratum; the poInt / poDisc faces and the possibility marks ride the formers-tour vector (the same test file).

### 14.6.3 SLevelGE, SLevelLE, and the level marks

#### Formation

$$\begin{array}{c}
\frac{B \in \mathbb{Q} \quad R \text{ PathObservable} \quad thr \in \mathbb{Q}_{\geq 0} \cup \{\infty\}}{\text{SLevelGE}(B, R, thr) \text{ ForallSpec}} \text{SLEVELGE} \\
\\
\frac{B \in \mathbb{Q} \quad R \text{ PathObservable} \quad thr \in \mathbb{Q}_{\geq 0} \cup \{\infty\}}{\text{SLevelLE}(B, R, thr) \text{ ForallSpec}} \text{SLEVELLE} \\
\\
\frac{B \in \mathbb{Q} \quad R \text{ PathObservable} \quad thr \in \mathbb{Q}_{\geq 0} \cup \{\infty\}}{\text{SLevelMayBeGE}(B, R, thr) \text{ ExistsSpec}} \text{SLEVELMAYBEGE} \\
\\
\frac{B \in \mathbb{Q} \quad R \text{ PathObservable} \quad thr \in \mathbb{Q}_{\geq 0} \cup \{\infty\}}{\text{SLevelMayBeLE}(B, R, thr) \text{ ExistsSpec}} \text{SLEVELMAYBELE}
\end{array}$$

The *hard* former: for every full-mass law whose level of inconsistency is finite and at most  $thr$ , the expected value of  $R$  lies on the stated side of  $B$ . The threshold lives in the extended nonnegative rationals — syntactically a two-constructor sum (finite bound; infinity), so every consumer’s finite/instant case split is carried by shape — and the finiteness clause is one uniform formula, not a case split: redundant at finite thresholds, it does all the work at  $thr = \infty$ , where the quantifier ranges over the *support*, every behaviour not fully refused. That instance is the behavioural-prohibition face of the satisfaction judgment itself: take  $R$  the indicator of the bad event via `retPath`,  $thr = \infty$ ,  $B = 0$  on the LE side, and the probe says the upper probability of the bad event is zero. At  $thr = 0$  the quantifier reads the zero-inconsistency core. Every rung of the ladder is a lawful probe; no positivity premise exists beyond the threshold’s own nonnegativity.

The *Maybe* pair completes the family’s polarity: *some* full-mass admitted law within the level threshold attains the stated side of  $B$  — the level stratum’s possibility marks, new with this edition, read exactly as the probability and expectation marks (at  $thr = \infty$  the mark asserts attainment by some behaviour-law in the support). With them the mark roster of section 14.2 is polarity-total: every threshold family presents both faces.

Soft and hard are not rivals but the two dualities the semantic universe already stratifies. The soft former’s single-shot linear tests are a complete instrument, by Fenchel–Moreau duality, exactly on the convex composition core; level probes recover the whole quasiconvex blanket, by Penot–Volle level-set duality — and the gap has a witness: a quantile (value-at-risk) specification has every sublevel a half-space, hence is hard-expressible tolerance-by-tolerance, and is not convex, hence invisible to the soft former alone. The hinge between them has a machine-checked ancestor over the retired calculus-tier carrier: there, the finite-tilt family converges in order to the wall at the infinite endpoint (`livenessTilt_top` in the archived `su-functor-legacy` tree, with epi-convergence), which is this pair of formers stated at the threshold stratum; its restatement over the live semantic universe is owed alongside the level compile itself. The hard former’s completeness, by contrast, is a theorem the live universe already holds: a single instance denotes a rational-height gamble row, and finite conjunctions of exactly these, closed under directed suprema, generate every citizen of the universe (`General.iSup_gambleRows_eq_self`) — the level probe is the universe’s own generation species wearing surface syntax, its certificate discharge the polynomial-nonnegativity species this book’s rule catalogue already discharges elsewhere, re-aimed.

#### API

The mechanized compile remains owed with the tilt-hinge restatement above; the producer surface below is landed, all four faces.

**TypeScript** `spec.levelGe / levelLe / levelMayBeGe / levelMayBeLe`

signature — `ts/src/spec.ts`

  q(7, 2),
  PathObservable::sup(StateObservable::poly(x1())),
  EnnRat::inf(),
);

```

## 14.6.4 SRateLE and SRateGE: event-rate envelopes

### Formation

$$\frac{\rho \in \mathbb{Q}_{\geq 0} \quad \sigma \in \mathbb{Q}_{\geq 0} \quad R \text{ TrList} \quad R \neq \text{nil}}{\text{SRateLE}(\rho, \sigma, R) \text{ ForallSpec}} \text{SRateLE}$$

$$\frac{\rho \in \mathbb{Q}_{\geq 0} \quad \sigma \in \mathbb{Q}_{\geq 0} \quad R \text{ TrList} \quad R \neq \text{nil}}{\text{SRateGE}(\rho, \sigma, R) \text{ ForallSpec}} \text{SRateGE}$$

The from-init affine count envelope — the rate axis’s first expectation-class citizens. Write  $N_t^R$  for the number of firings of the roster’s transitions on  $[0, t]$ : the same firing-metered counting the transition-count

functional reads (section 14.5.6), here horizon-parametric rather than whole-run, and consumed directly — the envelope is a family of bounds indexed by the horizon, not a single run-functional, which is why these formers take the roster itself. SRateLE claims that along every admitted law the expected count respects the envelope at every horizon — credal-upper expectation of  $N_t^R$  at most  $\rho t + \sigma$  for all  $t \geq 0$  — and SRateGE, the throughput face, that the credal-lower expectation dominates  $\rho t - \sigma$ . Both faces are floors at the ForallSpec cap: each bounds the whole credal body, and the claim direction selects the envelope — an upper count bound reads the upper prevision (the most events any compatible resolution produces), a lower bound the lower (the fewest). Both are certification pessimism, and rate atoms carry no attitude knob: the direction is the whole story. The possibility faces are deliberately absent, a recorded choice rather than an oversight: a mark-face rate envelope — *some* admitted law’s expected counts obey the envelope — has no certificate row family and no consumer, and the mark roster’s polarity-totality is a fact about the threshold families, which the envelope pair is not one of; a later widening stays additive.

The affine-from-init shape is the primitive on purpose. A bare long-run limit ( $\limsup_t N_t/t \leq \rho$ ) carries zero finite-window content — a consumer sized against it can be overwhelmed on any finite horizon — so the limit reading is a corollary of the envelope ( $\overline{E}[N_t]/t \leq \rho + \sigma/t$ ), never the interface object. And interval content is carried by *pairs*: a two-sided pair at matched rate — upper  $(\rho, \sigma_u)$ , lower  $(\rho, \sigma_l)$  — yields the interval envelope  $N_{(s,t]} \leq \rho(t-s) + \sigma_u + \sigma_l$  by pathwise subtraction, no ergodic machinery, which is why the primitive can stay from-init without losing burstiness control: a one-sided envelope says nothing about increments; a pair does. The remaining free laws are of the same grain: weakening an envelope weakens its claim (the upper face is monotone in both parameters; the lower face trades them the other way), and disjoint rosters sum — upper envelopes over disjoint rosters conjoin to an upper envelope at the summed parameters on the merged roster, pathwise count additivity plus subadditivity of the upper prevision — while the converse split is refused: a summed bound cannot be divided between rosters without a per-roster certificate, since all the mass may ride one of them.

Refusals, each with its reason. No limsup or ergodic primitive (the zero-finite-window-content argument above — and a fortiori no almost-sure empirical-rate convergence, a law of large numbers needing recurrence structure the vocabulary deliberately does not assume). Nothing sharper than the pair-derived interval form: equilibrium-rate claims and interval budgets below  $\sigma_u + \sigma_l$  genuinely need that same ergodic machinery — the fence the occupation-time operators sit behind (section 14.9.5). Counted events are declared transitions only, never predicate crossings: a full-rank diffusion crosses a surface infinitely often, so region-entry counting stays PCROSSSTREETT’s metered device (section 14.5.5) — a different species, not interchangeable. No within-roster order content: the envelope counts class firings, and per-item ordering or latency stays aggregate-invisible by design. No policy-quantified or optimality rate claims (“no dispatch achieves a better rate” is a research frontier, not a former): rate judgments are fixed-dispatch or demonic, like every judgment in this catalogue. And no attitude knob, as above. The assume/guarantee half of the rate axis — rate bounds crossing fused boundaries, and the probabilistic token-bucket budget form that rides fusion — remains a catalogued deliberate absence with its own registry slot (section 14.9.1).

*Compile.* The certificate species is staged beside the formers: a supermartingale row kit per face, kin to the drift rows everywhere above. The upper face’s kit carries a per-cell polynomial potential  $V$  with interior rows bounding the generator’s action on  $V$  plus the counted transitions’ intensity by  $\rho$  on each mode cell, counted-transition guard rows absorbing the unit charge ( $V$  after the reset at most  $V - 1$ ), un-counted guard rows non-increasing, and nonnegativity on the reset closure — making  $V + N_t^R - \rho t$  a supermartingale under every compatible law, so the expected count is at most  $\rho t + V(x)$ , envelopes last, with the certified region the sublevel  $\{V \leq \sigma\}$ . The lower face mirrors it ( $V + \rho t - N_t^R$ ; the counted compensator credits the count’s expected growth), and its potential is the Foster-Lyapunov throughput shape: a work-in-progress potential whose forced descent pays out completions. A third, structural route concludes the upper face from clock structure alone — race, dwell, and instant-budget readings of the landed timing stock, no potential synthesized. No exhibit claims a rate battery yet; formed claims await theirs, as everywhere in this catalogue.

*Witness for the demand:* the throughput claim of the Mini-Fab tutorial (section 17.4, chapter 17) renders as this former’s lower face; until this family was staged, that chapter could record the claim only as an argument beside the vocabulary.

## API

**TypeScript** ---

The theory rows are staged; the producer surface enters with the toolkit’s next revision, and this entry gains its quoted constructions then.

**Rust** ---

Likewise.

**14.6.5 SRegretLE and SRegretLEMark: seat regret****Formation**

$$\frac{\varepsilon \in \mathbb{Q} \quad \varepsilon \geq 0 \quad \pi \text{ System} \quad R \text{ PathObservable}}{\text{SRegretLE}(\varepsilon, \pi, R) \text{ ForallSpec}} \text{SREGRETLE}$$

$$\frac{\varepsilon \in \mathbb{Q} \quad \varepsilon \geq 0 \quad R \text{ PathObservable}}{\text{SRegretLEMark}(\varepsilon, R) \text{ ExistsSpec}} \text{SREGRETLEMARK}$$

The subject of a regret claim is a *comb*: a composite with exactly one seat — a hole presenting a declared interface, in the system side’s own vocabulary (chapter 12) — and the comparison class is the seat itself: every filler presenting that interface. The comparison class is read off the *subject*, never re-declared per formula — re-declaration would double-count it, and silent demonic closure of an unfilled hole under an ordinary claim is exactly what the pairing-relative demands refuse. Achieved and comparison values are credal-*lower* expectations of the run-functional on the respective closed composites: residual nondeterminism stays demonic on both sides uniformly — maximin regret, deliberately *not* online-learning pathwise regret, which needs a shared weather trace no compositional semantics supplies. The certificate face carries its reference filler: no type-correct filler beats  $\pi$  by more than  $\varepsilon$ , each judged by its own guaranteed value. The query face carries none — it is well-formed in total ignorance of the answer, and its discharging selection witness *carries* the filler: the angelic idiom, in which the witness is the answer. The two faces are the floor/mark duality one level up, with the quantifier moved from the law seat to the filler seat — which is why the name is MARK and not MAYBE: MAYBE is the law-seat existential, and the two seats have just been separated. Regret is one-sided by definition (no GE mirror: a “regret at least” face would be a liveness claim about the seat’s *spread* — a different former, deliberately not minted), and  $\varepsilon = 0$  is lawful and canonical: the exact-optimality claim. Pairing-relative demands — the paired subject carries exactly one hole; the certificate face’s filler fills it — mint at the certificate stratum, where the pairing is in hand.

*Witness for the demand*: the certified-Gymnasium “optimal, exactly” family — optimality claims the earlier edition could state only as bare return bounds against a known optimum; the discharge lanes are named with their species, not yet claimed.

**API****TypeScript** `spec.regretLeMark`

signature — `ts/src/spec.ts`

```
| export function regretLeMark(eps: QLike, ret: PathObservable): ExistsSpec
```

construction — `ts/tests/spec-native.test.ts`

```
| const markGe = s.probMayBeGe(Q.of(1, 2), s.always(band));
| const markRet = s.returnMayBeLe(0n, s.poSum(7, s.oChan(0)));
| const markLevel = s.levelMayBeGe(Q.of(1, 4), s.poAvg(s.oChan(1)), s.enFin(1n));
| const regretMark = s.regretLeMark(
|   Q.of(1, 100),
|   s.poDisc(s.oChan(0), Q.of(1, 20)),
| );
```

The safety face SREGRETLE has no producer former yet; the MARK is the landed surface, and the marks vector quoted here also drives the probability, return, and level MAYBE marks.

**Rust** `mtk_catalogue::spec::ExistsSpec::regret_le_mark`

signature — `crates/mtk-catalogue/src/spec/formula.rs`

```
| pub fn regret_le_mark(eps: WitRat, ret: PathObservable) -> Result<ExistsSpec, Refusal>
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let mark_ge = ExistsSpec::prob_may_be_ge(q(1, 2), PathPred::always(band.clone())).unwrap();
let mark_ret = ExistsSpec::return_may_be_le(
    q(0, 1),
    PathObservable::sum(7, StateObservable::chan(0)).unwrap(),
);
let mark_level = ExistsSpec::level_may_be_ge(
    q(1, 4),
    PathObservable::avg(StateObservable::chan(1)),
    EnnRat::fin(q(1, 1)).unwrap(),
);
let regret_mark = ExistsSpec::regret_le_mark(
    q(1, 100),
    PathObservable::disc(StateObservable::chan(0), q(1, 20)).unwrap(),
)
.unwrap();
```

The safety face SREGRETLE has no producer former yet; the MARK is the landed surface, and the marks vector quoted here also drives the probability, return, and level MAYBE marks.

## 14.7 Derived Spellings

Each entry here is a claim species from the certified corpus with its spelling in the grammar above — the catalogue’s evidence that *no further former is needed* for it. The helpers add no expressive power; where a helper has code, its definition is quoted, because the definition *is* the content. Two rows deliberately have no code in this wing, and say where their content lives instead. Each spelling owes the compile a coherence cell — the definitional rider saying the sugar’s class is the spelled form’s class. The first cells of this one-line class are machine-checked at the record site: bounded reach is trivially-safe until (`until0n_univ_safe`), and the recurrence sugar’s single trivial-request pair degenerates to reachability of the response region, conditioned on occupation, with the empty record exhibited as the one stage set where the readings part (`streett0n_singleton_univ_iff`, `streett0n_singleton_univ_empty`). The remaining spellings’ riders are named obligations of the same class, to land with the compile they annotate.

### 14.7.1 Capture within N steps

#### Spelling

$$\text{capture-within}(N, \varphi) = P_{\geq 1}[F_{\leq N} \varphi]$$

The credal view makes this worst-case over demonic branching and initial conditions — no dedicated former, no worst-case variant. *Witness*: the pendulum swing-up row — capture within 139 steps from every default-reset initial state.

#### API

**TypeScript** `spec.derived.captureWithin`

signature — `ts/src/spec.ts`

```
| captureWithin(steps: QLike, capture: StatePred): ForallSpec
```

definition — ts/src/spec.ts

```
/** Capture within `steps` — `P_{>=1}[F_{<=steps} capture]` as a
 * safety-face component (the credal stratum makes this worst-case
 * over demonic branching/init). */
captureWithin(steps: QLike, capture: StatePred): ForallSpec {
  return probGe(1n, deadline(steps, capture));
},
```

**Rust** mtk\_catalogue::spec::derived::capture\_within

signature — crates/mtk-catalogue/src/spec/derived.rs

```
pub fn capture_within(steps: WitRat, capture: StatePred) -> Result<ForallSpec, Refusal>
```

definition — crates/mtk-catalogue/src/spec/derived.rs

```
/// Wing C: capture within `steps` — `P_{>=1}[F_{<=steps} capture]`
/// (the credal stratum makes this worst-case over demonic
/// branching/init). Witness: the swing-up row — capture within 139
/// steps from every default-reset init.
pub fn capture_within(steps: WitRat, capture: StatePred) -> Result<ForallSpec, Refusal> {
  ForallSpec::prob_ge(rat_int(1), PathPred::deadline(steps, capture, false?))
}
```

## 14.7.2 Reach-then-hold (the funnel)

### Spelling

$\text{reach-then-hold}(p, T, \chi) = P_{\geq p}[F_{\leq T} \chi]$  where  $\chi$  is a child claim's certified invariance region

The outer transit is spelled here; the citation of the child's certified region ( $\chi$  as a region atom, concluded by a  $P_{\geq 1}[G \text{ band}]$  claim) belongs to the judgment stratum — the tower discipline again. *Witness*: the swing-up composition (outer transit into the held upright set); the LunarLander attitude funnel.

### API

**TypeScript** spec.derived.reachThenHold

signature — ts/src/spec.ts

```
reachThenHold(p: QLike, t: QLike, heldRegion: StatePred): ForallSpec
```

definition — ts/src/spec.ts

```
/** Reach-then-hold (funnel) — `P_{>=p}[F_{<=t} chil]` where `chi` is
 * a child claim's certified invariance region, cited as a region
 * atom (the citation itself rides the judgment stratum). */
reachThenHold(p: QLike, t: QLike, heldRegion: StatePred): ForallSpec {
  return probGe(p, deadline(t, heldRegion));
},
```

**Rust** mtk\_catalogue::spec::derived::reach\_then\_hold

signature — crates/mtk-catalogue/src/spec/derived.rs

```
pub fn reach_then_hold(
  p: WitRat,
  t: WitRat,
  held_region: StatePred,
) -> Result<ForallSpec, Refusal>
```

definition — crates/mtk-catalogue/src/spec/derived.rs

```

/// Wing C: reach-then-hold (funnel; band-hold) -
/// `P_{>=p}[F_{<=t} chi]` where `chi` is the *certified invariance
/// region* of a child claim (`P_{>=1}[G band]`), cited as a region
/// atom (tower citation: a child's certified region is a parent's
/// atom). This helper spells the outer transit; the citation itself
/// rides the judgment stratum. Witness: the swing-up composition;
/// the LunarLander attitude funnel.
pub fn reach_then_hold(
  p: WitRat,
  t: WitRat,
  held_region: StatePred,
) -> Result<ForallSpec, Refusal> {
  ForallSpec::prob_ge(p, PathPred::deadline(t, held_region, false?))
}

```

### 14.7.3 Safety until deadline

#### Spelling

$$\text{safe-until-deadline}(T, \text{safe}, \text{target}) = \text{safe } U_{\leq T} \text{target}$$

Directly the until former — or, for a probabilistic core, the two-story tower around it. Listed because the species recurs in the corpus under this name. *Witness*: the worked example; the until-battery fixtures.

#### API

##### TypeScript spec.derived.safetyUntilDeadline

signature — ts/src/spec.ts

```
| safetyUntilDeadline(t: QLike, safe: StatePred, target: StatePred): PathPred
```

definition — ts/src/spec.ts

```

/** Safety until deadline - `safe U_{<=t} target`, directly. */
safetyUntilDeadline(t: QLike, safe: StatePred, target: StatePred): PathPred {
  return until(t, safe, target);
},

```

##### Rust mtk\_catalogue::spec::derived::safety\_until\_deadline

signature — crates/mtk-catalogue/src/spec/derived.rs

```

pub fn safety_until_deadline(
  t: WitRat,
  safe: StatePred,
  target: StatePred,
) -> Result<PathPred, Refusal>

```

definition — crates/mtk-catalogue/src/spec/derived.rs

```

/// Wing C: safety until deadline - `safe U_{<=t} target`, directly
/// (or as the probability cap around it, which is a composition of
/// [`ForallSpec::prob_ge`] with this). Witness: the worked example;
/// until-battery fixtures.
pub fn safety_until_deadline(
  t: WitRat,
  safe: StatePred,
  target: StatePred,
) -> Result<PathPred, Refusal> {
  PathPred::until(t, safe, target)
}

```

## 14.7.4 Almost-sure recurrence under demonic input

### Spelling

$$\text{recurrence-as}(\gamma) = P_{\geq 1}[GF \gamma], \quad GF \gamma = PDwellStreett(PairBase(STrue, \gamma))$$

The dwell-metered Streett sugar at the demonic profile (frequently is step-frequently at unit ticks): the credal view reads the lower probability over the branch set, so almost-sure recurrence under an adversarial input needs no game former. *Witness*: the 219 circuit tasks, whose conjunctions of recurrence goals are built by exactly the quoted spelling.

### API

**TypeScript** `spec.derived.recurrenceAs`

signature — `ts/src/spec.ts`

```
recurrenceAs(gamma: StatePred): ForallSpec
gf(gamma: StatePred): PathPred
fg(phi: StatePred): PathPred
```

construction — `ts/tests/spec-native.test.ts`

```
const gamma0 = s.unwrap(s.derived.boolWireSet(0, 2));
const gamma1 = s.unwrap(s.derived.boolWireSet(1, 2));
const recur0 = s.derived.recurrenceAs(gamma0);
const recur1 = s.derived.recurrenceAs(gamma1);
```

**Rust** `mtk_catalogue::spec::derived::recurrence_as`

signature — `crates/mtk-catalogue/src/spec/derived.rs`

```
pub fn recurrence_as(gamma: StatePred) -> Result<ForallSpec, Refusal>
pub fn gf(gamma: StatePred) -> Result<PathPred, Refusal>
pub fn fg(phi: StatePred) -> PathPred
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let gamma0 = derived::bool_wire_set(0, 2).unwrap();
let gamma1 = derived::bool_wire_set(1, 2).unwrap();
let recur0 = derived::recurrence_as(gamma0).unwrap();
let recur1 = derived::recurrence_as(gamma1).unwrap();
```

## 14.7.5 Min-return over enumerated branches

### Spelling

$$\text{min-return}(B, R) = SReturnGE(B, R) \quad \text{at the credal reading}$$

Lower expectation over a finite branch set is the minimum — the spelling is the plain former; the worst-case reading belongs to the substrate, not the syntax. *Witness*: the Atari circuit rows (per-lane returns, claimed bound equal to the minimum, exact).

### API

**TypeScript** `spec.derived.minReturnOverBranches`

signature — `ts/src/spec.ts`

```
| minReturnOverBranches(lo: QLike, ret: PathObservable): ForallSpec
```

```
definition — ts/src/spec.ts
```

```
/** Min-return over enumerated branches — `SReturnGE` at the credal
 * stratum (lower expectation over a finite branch set = the
 * minimum); the spelling is the plain former. */
minReturnOverBranches(lo: QLike, ret: PathObservable): ForallSpec {
  return returnGe(lo, ret);
},
```

**Rust** `mtk_catalogue::spec::derived::min_return_over_branches`

```
signature — crates/mtk-catalogue/src/spec/derived.rs
```

```
| pub fn min_return_over_branches(lo: WitRat, ret: PathObservable) -> ForallSpec
```

```
definition — crates/mtk-catalogue/src/spec/derived.rs
```

```
/// Wing C: min-return over enumerated branches — `SReturnGE` at the
/// credal stratum (lower expectation over a finite branch set = the
/// minimum); the *spelling* is the plain former over the given run
/// functional, the credal reading is the substrate's. Witness: the
/// Atari circuit rows (per-lane returns, claimed bound = the
/// minimum).
pub fn min_return_over_branches(lo: WitRat, ret: PathObservable) -> ForallSpec {
  ForallSpec::return_ge(lo, ret)
}
```

## 14.7.6 Worst-case-over-init

### Spelling

any former + a demonic initial box on the system side

No spec-side helper, by design: worst-case over initial conditions is a property of the *pairing*, spelled as a demonic initial box in the system's own vocabulary (chapter 12) and read through the credal view — the formula layer needs no worst-case former. *Witness*: the swing-up rows; the random-ODE uniform-over-parameter barrier (parameter box as an initial-box axis).

### API

**TypeScript** ---

Spelled on the system side (a demonic initial box declaration), not in this namespace; the credal reading supplies the worst case.

**Rust** ---

Likewise: a system-side declaration, deliberately without a formula-layer twin.

## 14.7.7 Hard event-count envelopes

### Spelling

$$\text{count-ceiling}(B, R) = \text{SReturnLE}(B, \text{retFireCount}(R))$$

The count ceiling is the plain expectation former at the transition-count functional (section 14.5.6): along every admitted law, the total count of roster firings is at most  $B$  — no new grammar, as this section's

charter demands. An earlier edition of this entry routed the species through the designed event-rate envelopes as their  $p = 1$  instance; the count spine landed first, the rate family's expectation atoms have since been staged in their own right (section 14.6.4), and the probabilistic budget form — the  $p = 1$  route — remains the deliberate absence it was (section 14.9.1); the ceiling stays the plain spelling above either way. *Witness for the demand*: structurally bounded resource-sharing net families; the plated-transfer discharge that concludes the ceiling is Rule Catalogue content.

## API

**TypeScript** `spec.returnLe / retFireCount`

The ceiling is the plain composition of landed formers, `returnLe(B, retFireCount(R))` — the transition-count injection's producer surface, both languages, lives with the run functionals (section 14.5.6).

**Rust** `mtk_catalogue::spec::{ForallSpec::return_le, PathObservable::fire_count}`

Likewise: `ForallSpec::return_le(B, PathObservable::fire_count(R))`, the empty roster refused at construction and at the decoded-artifact preflight alike.

### 14.7.8 Boolean-output atoms

## Spelling

$$\text{bool-wire-set}(i) = \text{SAtomGE}(1, x_i) \quad \text{bool-wire-clear}(i) = \text{SAtomLE}(0, x_i)$$

The 0/1 convention on Boolean-valued wires: no Boolean atom former exists or is needed. *Witness*: the circuit suite's atoms compile to exactly this form; the liveness vector's recurrence goals are built over these spellings.

## API

**TypeScript** `spec.derived.boolWireSet / boolWireClear`

signature — `ts/src/spec.ts`

```
boolWireSet(index: number, width: number): Result<StatePred, SpecRefusal>
boolWireClear(index: number, width: number): Result<StatePred, SpecRefusal>
```

construction — `ts/tests/spec-native.test.ts`

```
const gamma0 = s.unwrap(s.derived.boolWireSet(0, 2));
const gamma1 = s.unwrap(s.derived.boolWireSet(1, 2));
const recur0 = s.derived.recurrenceAs(gamma0);
const recur1 = s.derived.recurrenceAs(gamma1);
```

**Rust** `mtk_catalogue::spec::derived::bool_wire_set`

signature — `crates/mtk-catalogue/src/spec/derived.rs`

```
pub fn bool_wire_set(index: usize, width: usize) -> Result<StatePred, Refusal>
pub fn bool_wire_clear(index: usize, width: usize) -> Result<StatePred, Refusal>
```

construction — `crates/mtk-catalogue/tests/golden_spec.rs`

```
let gamma0 = derived::bool_wire_set(0, 2).unwrap();
let gamma1 = derived::bool_wire_set(1, 2).unwrap();
let recur0 = derived::recurrence_as(gamma0).unwrap();
let recur1 = derived::recurrence_as(gamma1).unwrap();
```

## 14.8 The Rewrite Layer

### 14.8.1 Rewrite chains, concluding spec equivalence

#### Rules

Eighteen rewrite rules, each a denotation *equality* over  $\omega$ -words, with congruence (rewriting at a position) and chain transport (a sequence of rewrites transports satisfaction verbatim, in both directions): implication elimination, right distribution, double negation, the two De Morgan laws, negation past F/G/X, and the polarity-absorption fusion family — the existential-over-time operators absorb  $\vee$  and the universal-over-time operators absorb  $\wedge$ . Its charter member is the GF-disjunction fusion

$$\text{GF}(\varphi \vee \psi) = \text{GF } \varphi \vee \text{GF } \psi$$

(infinitely-often of a union is a union of infinitely-often, by pigeonhole); its siblings are F of a disjunction, G of a conjunction, FG of a conjunction, until with disjointed targets

$$(\sigma \text{ U } \tau_1) \vee (\sigma \text{ U } \tau_2) = \sigma \text{ U } (\tau_1 \vee \tau_2)$$

(the target position is existential), until with conjoined safety arguments

$$(\sigma_1 \text{ U } \tau) \wedge (\sigma_2 \text{ U } \tau) = (\sigma_1 \wedge \sigma_2) \text{ U } \tau$$

(the safety position is universal), and the bounded-horizon ( $\leq T$ ) siblings of the four fusions that carry a horizon — the  $\leq T$  decorations carry through the witness arithmetic verbatim, while FG has no bounded row: its settling time is unbounded by construction. The absorption boundary is exact, and the fence is theorem-backed rather than asserted: the four wrong-polarity fusions — F of a conjunction, G of a disjunction, and their GF/FG counterparts — are machine-refuted by explicit  $\omega$ -word counterexample theorems in both provers (`no_f_and_fusion`, `no_g_or_fusion`, `no_gf_and_fusion`, `no_fg_or_fusion`). A chain is a typed citation: rule, position, direction, step by step; it concludes the judgment `QSpecEquiv(a, b)` below. The concluded judgment is already a row species of the normative schema; the chain citation's own row species is owed there, and until it lands a chain is a wire artifact of the producer surface.

All eighteen rules are proved in Lean *and* in HOL4, statement for statement, with no incomplete proofs; completeness is proven for the benchmark liveness fragment — every spec of that suite's grammar reaches the consumable normal form, witnessed mechanically by all 219 verbatim specs normalizing and re-validating in an independent checker. Carrier genericity varies by rule family: eight of the eighteen rules are per-position Boolean and duality laws whose equalities hold over any linearly ordered time carrier; the nine fusion rules beyond GF — five unbounded, four bounded-horizon — are finite-witness manipulations whose equalities hold over any unbounded linear time carrier; the GF-fusion remains the only pigeonhole rule, needing infinitely-often as cofinal occurrence; the next-step duality carries the step-structure requirement of its operator, which enters the row grammar together with that operator. The machine-checked proofs are the  $\omega$ -word instances; the carrier-generic restatements are small named obligations. One further restatement belongs to this chapter's own compile, and its ground floor is now machine-checked (`SuFunctor.Universe.SpecRewrite`): soundness at the universe means the compiled spec classes of a rule's two sides coincide, and that warrant is strictly stronger than denotation equality — a disjunction and an atom of the same denotation compile to different classes, because models may hedge (`exists_denEq_not_classEq`, the compiled image of the hedging gap) — so class-level soundness travels by term structure: the class semantics is a homomorphism of the normal-form lattice (commutation, association, distribution, and — against the hedging intuition — absorption, each landed as a class equality), and the normal-form dualities are sound for the sharper reason that they do not move the term at all (`classEquiv_of_nnf_eq`); the obstruction lives at the region-to-class seam and nowhere else. That development settles the state stratum. The eighteen temporal rules' own class-level restatement, one row up over the path formers' compile, remains an obligation this edition names rather than claims.

The producer surface *constructs* chains — it deliberately does not apply rewrites. The checker replays the chain; a chain the constructor accepts is a well-formed citation, not a verified equivalence; an empty chain refuses (reflexivity is not a chain). Application code is withheld on purpose while the deadline-fragment

deductive calculus (bounded-reach/always equivalences over clocked classes) remains live research: frozen application rows would re-mint the sidecar disease one level up.

Cross-carrier *application* is not a rewrite matter at all: a step-structured spec applied to a continuous-time system is expressed by composing the system with a sampler mechanism and asserting the spec of the sampled composite, with claims related across the pair by the simulation-transport rule of chapter 15 — zero new machinery. The certified LunarLander pair (one value table, both tick semantics, jitter priced at a factor 2.66 in ticks-to-funnel) is the landed witness of this pattern.

*Witness*: 219 rewrite-chain artifacts asserting spec equivalence for the liveness suite — the demand that shaped the row form quoted below.

## API

### TypeScript spec.rewriteChain

signature — ts/src/spec.ts

```
export function rewriteChain(
  a: SpecRef,
  b: SpecRef,
  steps: ReadonlyArray<RewriteStep>,
): Result<Artifact, SpecRefusal>
```

construction — ts/tests/spec-native.test.ts

```
const art = s.unwrap(
  s.rewriteChain(j.specRef("spec-as-stated"), j.specRef("spec-normal-form"), [
    {
      rule: "implicationElim",
      at: [{ kind: "specForall", i: 0 }],
      dir: "forward",
    },
    {
      rule: "gfDisjunctionFusion",
      at: [{ kind: "specForall", i: 0 }, { kind: "andArg", i: 1 }],
      dir: "forward",
    },
  ]),
);
```

### Rust mtk\_catalogue::spec::rewrite::RewriteChainV0::new

signature — crates/mtk-catalogue/src/spec/rewrite.rs

```
pub fn new(a: SpecRef, b: SpecRef, steps: Vec<RewriteStep>) -> Result<Self, Refusal>

pub fn concludes(&self) -> QSpecEquiv
```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```
let chain = RewriteChainV0::new(
  SpecRef("spec-as-stated".into()),
  SpecRef("spec-normal-form".into()),
  vec![
    RewriteStep {
      rule: RewriteRule::ImplicationElim,
      at: FormulaPath(vec![Step::SpecForall(0)]),
      dir: Direction::Forward,
    },
    RewriteStep {
      rule: RewriteRule::GfDisjunctionFusion,
      at: FormulaPath(vec![Step::SpecForall(0), Step::AndArg(1)]),
      dir: Direction::Forward,
    },
  ],
)
.unwrap();
let concluded = chain.concludes();
```

## 14.9 Deliberate Absences

A catalogue that only listed what exists would invite spelling every missing claim species as prose — the sidecar disease by another door. This section records what the formula layer deliberately does *not* provide, why, and what would unlock each. In rule form an absence is the absence of a formation rule (or of a compile clause for a formable term), and several are enforced in code, as typing-preflight refusals that name their fence; the negation-residue absences additionally carry the no-expressible-complement warrant of section 14.2 — they are theorems about the class algebra, not prudence. The admission rule stands: each of these gains its former when its first certificate lane arrives, and this catalogue is the registry where that admission is recorded.

### 14.9.1 Event-rate assume/guarantee; the probabilistic budget form

#### Absence

The expectation-envelope atoms of the rate family are staged (section 14.6.4); this slot keeps what remains absent, which is everything that crosses a fused boundary. Rate *assumptions* and *guarantees* as interface fields — a producer's guaranteed output envelope becoming a fused neighbour's assumed input envelope, with the transported bound recomputed by the checker as affine arithmetic in  $(\rho, \sigma)$  — wait on the event-port vocabulary of the system side and enter with the first fused-boundary composite, together with their composition rule and its acyclicity oracle. The *probabilistic* budget form — a time-uniform claim that the count never overdraws its budget, with probability at least  $p$  — is sugar over a token-bucket monitor mechanism fused into every counted firing, riding the safety kernel unchanged; it waits on the same fusion vocabulary, and the hard  $p = 1$  envelope with it. Cyclic rate reasoning across a feedback loop is refused even then: naive fixpoints are unsound, the sound discharge is induction over time, and that rule enters on its own warrant or not at all. None of this fences the staged atoms or the count spine — what this absence still fences is boundary-crossing rate reasoning and probabilistic budgets, not counts and not expectation envelopes.

#### API

##### TypeScript ---

No constructor exists for the boundary-crossing forms; the staged atoms carry the family's admission (section 14.6.4), and this entry is the residue's registry slot.

##### Rust ---

Likewise.

### 14.9.2 Interior upper-bound consumption; Rabin; negated Streett and until

#### Absence

Formation of probability upper bounds is open (SPROBLE above): the direct  $P_{\leq q}$  claim is a closed constraint of the same species as the GE face, and fencing its formation as if it were a complement over-read the negation fence. What remains absent is narrower, and two different things. *Consumption* of an upper bound at interior  $q$  over an under-determined model needs certificate towers that *over*-approximate denotations — the dual of the entire under-approximation machinery this stack ships; the exact lane discharges the  $q = 0$  instance today (the same backward-induction table, read in the super-solution direction), and interior  $q$  waits for the tower. Rabin acceptance (the negation of Streett) and path-negated Streett or bounded-until remain genuinely fenced by the negation residue: under the properness presupposition no spec class has an expressible complement (section 14.2), so there is no class-level object for those dual rules to conclude into — the missing rules are missing mathematics. The typing preflight still refuses each *negation* residue with a

path address (a complemented probability is lawful only as a Streett request consumed through PairCmpl); the direct LE former needs no refusal, because it was never a negation.

## API

**TypeScript** `spec.proble`

The LE former constructs (`proble`, quoted at its entry); the preflight refusals (`negPathAtomEvenPolarity`, `negStreett`, `negUntil`) remain the surface for the negation residues, whose entry points are quoted under `SNOT`.

**Rust** `mtk_catalogue::spec::ForallSpec::prob_le`

Likewise (`Refusal::NegPathAtomEvenPolarity` and `kin`, with formula-path geometry).

### 14.9.3 Stochastic bounded-always at even parity

## Absence

The former constructs today (`PALwaysT` above); what is absent is stochastic *consumption* at even parity — the same over-approximating tower machinery as the probability upper bounds. Deterministic consumption is immediate now; the spellability of the statement was the point of drafting the former ahead of its full battery.

## API

**TypeScript** ---

The former's constructor is quoted under `PALwaysT`; no additional surface exists for the fenced consumption.

**Rust** ---

Likewise.

### 14.9.4 Unbounded quantitative reach

## Absence

$$F\varphi \rightsquigarrow F_{\leq T}\varphi \quad \text{at a producer-chosen } T, \text{ flagged producer } T$$

No unbounded-reach primitive: the spelling is a producer-chosen deadline, sound as an under-approximation and *flagged as such* in the row, so a certificate reader can always tell a bounded claim made for its own sake from a bounded claim standing in for an unbounded one. A complete almost-sure-termination battery is the named unlock for the primitive form.

## API

**TypeScript** `spec.derived.eventuallyProducerHorizon`

signature — `ts/src/spec.ts`

| `eventuallyProducerHorizon(horizon: QLike, arg: StatePred): PathPred`

definition — `ts/src/spec.ts`

```

/** The `producerT` spelling of unbounded reach: `F phi` compiled as
 * `F_{<=horizon} phi` at a producer-chosen horizon – a sound
 * under-approximation, flagged as such in the row. */
eventuallyProducerHorizon(horizon: QLike, arg: StatePred): PathPred {
  return deadline(horizon, arg, { producerT: true });
},

```

**Rust** `mtk_catalogue::spec::derived::eventually_producer_horizon`

signature — `crates/mtk-catalogue/src/spec/derived.rs`

```
pub fn eventually_producer_horizon(horizon: WitRat, arg: StatePred) -> Result<PathPred, Refusal>
```

definition — `crates/mtk-catalogue/src/spec/derived.rs`

```

/// The `producerT` spelling of unbounded reach: `F phi` compiled as

  PathPred::deadline(horizon, arg, true)
}

```

## 14.9.5 Occupation-time and duration operators

### Absence

Narrowed by the theory revision: much of what this absence used to fence is now spellable compositionally. Integrated occupation time is the time integral of a region’s indicator (`poInt` over `oInd`), the long-run occupation fraction is its average (`poAvg` over `oInd`), and dwell-metered acceptance is a former of its own (`PDWELLSTREETT`). What remains absent is *dedicated* sojourn and per-visit-duration operators — claims about individual visits rather than accumulated occupation — withheld pending a kernel theorem: occupation-measure mechanics are the natural substrate, and a former without its kernel would be a claim nothing can certify. The compositional spellings above share the constraint at one remove: their certificate lanes are named, not yet claimed.

### API

#### TypeScript ---

The compositional spellings construct on the landed injection and accumulator surfaces (quoted at their entries); the dedicated operators remain withheld pending the kernel theorem — nothing further to construct.

#### Rust ---

Likewise.

## 14.9.6 Nested path quantification

### Absence

The descending grid arrows: path-quantified material re-entering the atemporal row as a state label —  $\mathbb{P}_{\geq q}[\psi]$  as a state predicate, a value functional as a state observable — the CTL/PCTL nesting style. This is the grid’s one deliberate absence (section 14.2), and its warrant has two layers. The *raw* formers are fenced by the geometry: a single level of re-entry exits the constructible classes (neither face’s rooted class is a crescent), and the negation fence forbids deriving the universal face from the existential one — raw nesting is not a missing feature but a shape the class algebra refuses, and any future admission must carry both faces as primitives (the analysis is mechanized in the adequacy layer’s path-to-state development). The

*principled* route — certified-citation formers, the tower discipline promoted to a formation rule, Observable column first — is semantically supported (the behavioural tier already denotes the descending arrows) and deliberately out of scope for this edition: planned for the language’s second major revision (2026Q4), a scoped fence chosen with the open pathway in full view. The certified corpus’s nesting needs are served through the judgment stratum — a child claim’s certified region cited as a parent’s StatePred atom, the tower discipline (entry SPROBGE) — so the absence fences only the syntactic embedding, which no landed artefact ever spelled.

## API

### TypeScript ---

No constructor exists, deliberately; the certified-citation former family is scheduled with the second major revision.

### Rust ---

Likewise.

## 14.9.7 Strategy quantification

### Absence

Controlled and game forms are absent from the formula layer by design: open nondeterminism is absorbed by the credal reading, and policy-level quantification is a judgment-layer and system-side question (chapter 12, the decision-process rows). The formula layer stays closed-system — a strategy quantifier would bind at the wrong stratum.

## API

### TypeScript ---

No strategy quantifier exists in this namespace, by design.

### Rust ---

Likewise.

## 14.9.8 Delays

### Absence

Permanently out of the formula layer: a delay is a model-class change (history-dependent state), not a formula-class change. If it arrives, it arrives as a new mechanism species with its own certificate shapes on the system side — never as a former here.

## API

### TypeScript ---

Out of scope for the formula layer, permanently.

### Rust ---

Likewise.

## 14.10 Judgment Kinds

A *judgment kind* is a  $\models$ -side sort — the type a certificate’s rules conclude into — and each kind carries its own small sub-logic: the premises it takes, the machinery that discharges it (*rule*: a rule node concludes it; *oracle*: a registry-pinned recompute; *chase*: load-time axioms, in the row schema’s three modes — chase proper *derives* rows, report-mode axioms state loud constraints, and refuse-mode axioms gate admission), and the consumers that cite it. The row schema reads this section’s inventory as three verbs: a revision *states* a satisfaction claim (a system paired with a spec), *compiles* it into the two-polarity verdict form (its entry below), and *discharges* it through battery and rule-node rows a checker replays. Homing these at the judgment stratum is a design statement: the formula is about the system; these are about the claim’s kind and evidence. At the semantic universe the satisfaction sort’s meaning is the fibre order itself (SuFunctor.Universe.Sat: the spec’s belief lies below the system’s), with the properness presupposition carried structurally, per section 14.1; the splice of the certified checker’s acceptance judgment into that order is named in the assurance ledger rather than claimed here — its stated prerequisite, the certificate schema’s absorption of this chapter’s redesign, has landed. The citation discipline that every kind below leans on — a premise accepts base-tower proof leaves, or concluded-judgment references of a stated kind, or certificate data, and never a mixture — is deliberately not an entry here: it is the edge discipline whose warrant is the induction over admitted derivations itself, and it renders at the end of chapter 15 as the soundness theorem the kinds feed.

Producer-side, every kind below is a versioned wire artifact (a literal schema name and version, exact rationals as canonical text, unknown fields ignored on read), emitted through the one canonical encoder. What is deliberately *not* here, recorded so nobody re-adds it: no second sort for interface-indexed satisfaction (see the next two entries); no tower-step kind (its content is a region satisfaction consumed through a premise field); no mixing-rate kind (named open); no attitude judgment kind (the attitude blend is a record component that no rule concludes and nothing consumes — the closing entry).

### 14.10.1 QSat: root satisfaction

#### Formation

$$\frac{s \text{ Spec} \quad M \text{ System} \quad \text{states}(M) \simeq \text{wire object of } s}{M \models s \text{ Judgment}} \text{ Q}_{\text{SAT}}$$

Root satisfaction, closed *and* interface-indexed: one judgment kind for both readings. A spec with no interface row is closed; with one, the assumption region reads input wires, the guarantee reads output wires, and the spec’s interface must equal the system’s presented interface (an agreement axiom, chase-policed at the pairing). The formerly mooted second sort for interface-indexed satisfaction is *dissolved*: the closed judgment is the empty-interface instance, so one kind suffices and the loader cannot be handed a claim whose reading is ambiguous.

Under the properness presupposition a root satisfaction claim asserts *safe and proper*: to satisfy anything, first exist. The conjunct is the judgment’s presupposition, carried by the compile target’s type (SpecAtom.top\_mem; emitted unconditionally, elabSpec\_top\_mem) — zero syntax cost, one nonemptiness discharge per root claim, discharged at use sites, with emptiness certificates the optional schema slot. This is the spec-side face of the guard whose system-side face reads an inconsistent system as satisfying all safety specs and no liveness specs (top\_notMem\_modelClass; ex falso inverts structurally, never by a rule). Sub-logic: concluded from a region-satisfaction row plus exact rational evaluation on the initial region (the satisfaction-from-region rule of chapter 15); transported across wirings with slack arithmetic by the assume-guarantee composition rules.

One satisfaction-stratum variant deserves its sentence here, because it is certificate machinery and must not be mistaken for formula grammar: a *guarded* satisfaction claim conditions the guarantee on an initial-region antecedent — demanded of every admitted law whose initial marginal is supported in the cited region, with nothing promised off-region. The guard is a predicate *on* the subject’s initial data, not initial data

(the record still binds no model), and the class algebra stays complement-free: the antecedent is a ground condition on system data, never a behaviour class, which is why no implication former exists below the cap. Its introduction rule discharges the initial-membership hypothesis *into* the claim; its record row cites the certificate-side region vocabulary and lives with the certificate sections of the normative theory — the subject strata stay certificate-citation-free by the standing deliberate absence — and its introduction and elimination are Rule Catalogue content.

*Witness*: every root certificate; the composition chapters' worked examples exercise the interface-indexed reading end to end.

## API

### TypeScript judgment.sat

signature — ts/src/judgment.ts

```
export function sat(args: { sys: SysRef; spec: SpecRef }): Result<
  Artifact,
  JudgmentRefusal
>
```

construction — ts/tests/spec-native.test.ts

```
s.unwrap(j.sat({ sys: j.sysRef("sys-a"), spec: j.specRef("spec-a") })),
```

### Rust mtk\_catalogue::judgment::QSat::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
pub fn new(sys: SysRef, spec: SpecRef) -> Self
```

construction — crates/mtk-catalogue/tests/roundtrip\_spec.rs

```
let sat = QSat::new(SysRef("sys-a".into()), SpecRef("spec-a".into()));
```

## 14.10.2 Interface-indexed satisfaction, defined

### Definition

For a system  $\Sigma$  and an interface spec  $(I, \alpha, \gamma[\cdot, \kappa])$  — assumptions  $\alpha$  on input wires, guarantee  $\gamma$  on output wires, optional slack  $\kappa$  — the judgment  $\Sigma \models_I (I, \alpha, \gamma[\cdot, \kappa])$  asserts that every behaviour of  $\Sigma$  whose inputs conform to  $\alpha$  delivers  $\gamma$  (with margin per  $\kappa$  where declared); in the stochastic profiles, almost every behaviour, with failure measured *within the conforming event*:

$$\forall^\mu \omega, \omega \in \text{conform} \rightarrow \omega \in \text{sat}; \quad \text{quantitatively} \quad \mu(\text{conform} \cap \text{sat}^c) \leq \varepsilon.$$

Unlike the closed judgment  $\mathcal{M} \models s$ , which quantifies unconditionally over all behaviours from the initial region,  $\models_I$  quantifies conditionally — satisfaction relativized to the interface; the closed judgment is its empty-interface instance. The subscript is a roman kind-marker, not a parameter, following the global-stratum marker  $\models_D$  (entry QMORSE).

This reading is defined once, here, and has *no schema sort of its own*: its home is QSat whose spec carries an interface; assumptions and slack live on the spec record; interface agreement is the pairing's chase axiom. It earns an entry because it is a genuinely different satisfaction relation — conditional, with failure measured inside the conforming event — and because the composition rules' conclusions are exactly of this shape. Its mechanization status: the sequent substrate for the satisfaction judgment carries the properness conjunct as a theorem (the pair-sequent development, SuFunctor.Universe.PairSequent), and the record-level compile carries assumptions as data with their conditional semantics deferred fail-closed (section 14.3.1); the relativized reading stated at the semantic universe is a named obligation, not yet claimed.

## API

**TypeScript** ---

Carried by `judgment.sat` with an interface-carrying spec — deliberately no separate entry point.

**Rust** ---

Carried by `QSat` likewise; the dissolved second sort is recorded in the module documentation so nobody re-adds it.

**14.10.3 The compiled verdict form****Definition**

$$\text{QVerdictForm} : [\text{floors} : \text{QRegionSat}^*, \text{marks} : \text{QRegionSat}^*]$$

A compiled satisfaction verdict carries its demand atoms in *two* lists, and the split is schema content because it is not recoverable from the atoms alone: the same constraint species denotes differently per face. A *floor* holds over the whole credal body; a *mark* asserts that some admitted law attains — so folding the two into one list would erase exactly the distinction the denotation reads. Polarity is *declared* at formation — the cap sorts of section 14.2 — and *discharged* here: one home per stratum, connected by the compile. No battery or region sort carries a polarity flag; the two lists are the verdict-side home, with the floors compiled from the `ForallSpec` components and the marks from the `ExistsSpec` list plus the unconditional properness mark — attitude components take no part in the form, because a design score is not a verdict — and the form’s agreement with the declared faces is part of the recompute obligation below. The mark list is the verdict’s existential conjunct, first-class: an *empty* mark list is the all-safety claim, true of the zero-mass subject, and a form that derived liveness from floor content would silently certify a dead subject live — which is why the record-level compile emits the properness mark unconditionally (`elabSpec_top_mem`, section 14.3.1), so a form compiling a root specification carries a nonempty mark list. Liveness demands enter the mark list as *negation walls*: the demand “at least  $q$ ” enters as the mark of its complement’s failure — the wall/dip pair of the compile target (section 14.1), as rows. The form is value-like; its attachment to a root claim is a zero-or-one relation (a claim with no form is simply not compiled); and the agreement between the form and the specification it compiles is a *recompute obligation* at the ground seam, never a trusted row: the checker re-derives the form from the spec it cites.

*Witness*: the staged certificate probes of the normative theory’s battery; corpus-wide re-emission follows the producer-side emitter, which has not landed.

**API****TypeScript** ---

No constructor is exposed: the form is compiled, not authored, and no producer-side emission exists yet.

**Rust** ---

Likewise.

**14.10.4 QSatConf: the confidence qualifier****Definition**

$$\text{QSatConf} : [\text{sys} : \text{System}, \text{spec} : \text{Spec}, \alpha : \mathbb{Q}], \quad 0 < \alpha < 1$$

The spec holds *up to the evidence's error budget*: the claim is backed by a betting-martingale ledger whose wealth crossed  $1/\alpha$ , and soundness is time-uniform — Ville's inequality [234] for nonnegative supermartingales plus a randomized-last-look refinement, both machine-checked in the Lean auxiliary tree. This is a *distinct kind*, not a field on QSat: confidence-qualified rows are never silently mixed with exact or almost-sure rows — a sort distinction the loader cannot blur, rather than a rendering convention. Sub-logic: rule (ledger rows in, judgment out); the range demand on  $\alpha$  is a report-mode constraint at load, both ends strict ( $\alpha = 0$  would claim the exact tier in statistical clothes;  $\alpha = 1$  claims nothing). Ledger emission belongs to the statistical harness on the system side; this row is the claim it backs.

*Witness*: the LunarLander statistical rows —  $\mathbb{E}[R] \geq 236.577$  at  $\alpha = 1/20$  over  $10^6$  episodes, checked at nanoseconds per obligation; the continuous variant's certified floor exceeding the discrete variant's empirical mean.

## API

### TypeScript judgment.satConf

signature — ts/src/judgment.ts

```
export function satConf(args: {
  sys: SysRef;
  spec: SpecRef;
  alpha: QLike;
}): Result<Artifact, JudgmentRefusal>
```

construction — ts/tests/spec-native.test.ts

```
const art = s.unwrap(
  j.satConf({
    sys: j.sysRef("lunarlander-cont"),
    spec: j.specRef("return-floor-236577/1000"),
    alpha: Q.of(1, 20),
  }),
);
```

### Rust mtk\_catalogue::judgment::QSatConf::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
pub fn new(sys: SysRef, spec: SpecRef, alpha: WitRat) -> Result<Self, Refusal>
```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```
let row = QSatConf::new(
  SysRef("lunarlander-cont".into()),
  SpecRef("return-floor-236577/1000".into()),
  q(1, 20),
)
.unwrap();
```

## 14.10.5 QSpecEquiv: spec equivalence

### Definition

$$\text{QSpecEquiv} : [a : \text{Spec}, b : \text{Spec}]$$

Two specs denote the same property over every behaviour carrier on which both are interpretable. The judgment stores *no semantics-class field*, deliberately: a stored three-way class enum misstates the structure (an  $\omega$ -word is a càdlàg trajectory under the piecewise-constant-at-integer-times embedding, so the classes are not disjoint). Instead, **carrier scope is derived, never stored**: it is the carrier-requirement synthesis judgment of section 14.2 — each former's  $\triangleright$  annotation — with an equivalence judgment's scope the intersection of its two sides' requirements. An empty intersection is a conformance refusal at the consumer,

not a judgment. The Return stratum’s split horizons are this distinction already encoded: tick-summed returns demand steps, integrated returns demand duration. Sub-logic: concluded by the rewrite layer’s chains (rule); the derived-requirement computation is part of the producer surface, quoted below the tour entries.

*Witness:* the 219 rewrite-chain artifacts of the liveness suite, each concluding exactly this judgment.

## API

### TypeScript judgment.specEquiv

signature — ts/src/judgment.ts

```
export function specEquiv(args: { a: SpecRef; b: SpecRef }): Result<
  Artifact,
  JudgmentRefusal
>
```

construction — ts/tests/spec-native.test.ts

```
s.unwrap(j.specEquiv({ a: j.specRef("spec-a"), b: j.specRef("spec-b") })),
```

### Rust mtk\_catalogue::judgment::QSpecEquiv::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
pub fn new(a: SpecRef, b: SpecRef) -> Self
```

construction — crates/mtk-catalogue/tests/roundtrip\_spec.rs

```
let equiv = QSpecEquiv::new(SpecRef("spec-a".into()), SpecRef("spec-b".into()));
```

## 14.10.6 QRegionSat: the workhorse

### Definition

$$\text{QRegionSat} : [\text{formula} : \text{StatePred}, \text{region} : \text{QRegionAtom}] \quad \forall x \in R : x \models_{\mathcal{M}} \varphi$$

with the region-atom vocabulary

$$\text{qraSublevel}(fam, \theta) \mid \text{qraBox}(\text{intervals}) \mid \text{qraAffine}\left(\sum_i c_i V_i \leq \theta\right).$$

Every state in the cited region satisfies the formula, with the kernel region *under*-approximating the formula’s denotation — one orientation suffices, since complement consumption inherits the over-approximation for free. The region atoms are how certified regions are *cited*: a sublevel set of a certified function family, an exact-rational box, or a sublevel of an affine combination of certified families. Sub-logic: concluded by the battery rules (safety, deadline, until, Streett), basins, union bounds, the NNF alias family, and region-combination nodes; battery well-formedness policed by oracles; consumed by the tower-citation edge discipline (a child’s concluded region is a parent’s atom) and by satisfaction-from-region.

*Witness:* the entire supermartingale corpus; the three quoted constructions are the committed vectors for the three atom variants.

## API

### TypeScript judgment.regionSat

signature — ts/src/judgment.ts

```
export function regionSat(args: {
  formula: StatePred;
  region: RegionAtom;
}): Result<Artifact, JudgmentRefusal>
```

construction — ts/tests/spec-native.test.ts

```
const phi = s.polyLe(0n, s.unwrap(s.polyVar(1, 2)));

const sub = s.unwrap(
  j.regionSat({
    formula: phi,
    region: j.sublevel(j.certFamRef("Lyap-v1"), 0.of(7, 5)),
  }),
);
```

The box and affine region-atom variants ride sibling committed vectors in the same tests.

**Rust** mtk\_catalogue::judgment::QRegionSat::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
pub fn new(formula: StatePred, region: RegionAtom) -> Self
```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```
let phi = StatePred::poly_le(q(0, 1), Poly::var(1, 2).unwrap());
let sublevel = QRegionSat::new(
  phi.clone(),
  RegionAtom::Sublevel {
    cert: CertFamRef("Lyap-v1".into()),
    thr: q(7, 5),
  },
);
```

The box and affine region-atom variants ride sibling committed vectors in the same tests.

## 14.10.7 QCapSat: the cap-on-region vehicle

### Definition

$$\text{QCapSat} : [\text{cap} : \text{ForallSpec}, \text{region} : \text{QRegionAtom}] \quad \forall x \in R : x \models_{\mathcal{M}} \text{cap}$$

A probability cap certified from a region: every state in the cited region satisfies the safety-face component, with the region *under*-approximating the cap's denotation — the workhorse's orientation, one entry up the formula grid. The kind entered at revision event 4 as a deliberately *interim* vehicle: the previous edition nested the probability former under the region workhorse's state formula, the formation grid makes that shape unrepresentable (a cap is a component, never a state predicate), and so the cap-discharging rules — batteries, transports, reach tables — conclude this kind instead. Revision event 6 discharges the interim framing. The normative theory stores those conclusions as attributes of the battery proof nodes themselves and ties caps to spec components by keying each satisfaction claim to the component's own entity row: `qsat_warrant` relates the claim to a `QForallSat` row carrying the component and its region. The producer's rule rows are re-staged against that seam — warrants are emitted entity-keyed, under a versioned species binding that refuses pre-revision closures at the seam, loudly, at derivation time. What no producer emits yet is the compiled verdict form (section 14.10.3 records the same absence), so this kind remains the typed conclusion the cap-discharging rules place on the wire.

*Witness:* the committed vector (the quoted construction, both languages byte-identical); the battery conclusions across the corpus exercise the same shape.

### API

**TypeScript** judgment.capSat

signature — ts/src/judgment.ts

```
export function capSat(args: {
  cap: ForallSpec;
  region: RegionAtom;
}): Result<Artifact, JudgmentRefusal>
```

construction — ts/tests/spec-native.test.ts

```
s.unwrap(
  j.capSat({
    cap: s.probGe(Q.of(9, 10), s.always(phi)),
    region: j.sublevel(j.certFamRef("Lyap-v1"), Q.of(1, 10)),
  }),
),
```

Entered at revision event 4 as the interim typed conclusion for the cap-discharging rules (batteries, transports, reach tables); at revision event 6 the warrant seam is entity-keyed and the producer's rule rows are re-staged against it, and this kind remains the typed conclusion those rules place on the wire pending a verdict-form producer.

**Rust** mtk\_catalogue::judgment::QCapSat::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
pub fn new(cap: ForallSpec, region: RegionAtom) -> Self
```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```
let phi = StatePred::poly_le(q(0, 1), Poly::var(0, 1).unwrap());
let row = QCapSat::new(
  ForallSpec::prob_ge(q(9, 10), PathPred::always(phi)).unwrap(),
  RegionAtom::Sublevel {
    cert: CertFamRef("Lyap-v1".into()),
    thr: q(1, 10),
  },
);
```

Entered at revision event 4 as the interim typed conclusion for the cap-discharging rules (batteries, transports, reach tables); at revision event 6 the warrant seam is entity-keyed and the producer's rule rows are re-staged against it, and this kind remains the typed conclusion those rules place on the wire pending a verdict-form producer.

**14.10.8 QInvScope: invariance with scope****Definition**

$$\text{QInvScope} : [\text{region} : \text{QRegionAtom}, \text{init} : \text{QRegionAtom}] \quad S \text{ forward-invariant} \wedge X_0 \subseteq S$$

The region is forward-invariant and contains the initial set. Sub-logic: concluded by the block-invariance rule (strictly facet-inward cone rows plus containment) and its lattice alias; consumed by basins, by battery scope-warrant fields, and by the aggregate-scope kind's invariance route below. *Witness*: the invariance rows across the corpus; the Morse-stratum discharge kits cite it wherever a block's scope must be warranted.

**API****TypeScript** judgment.invScope

signature — ts/src/judgment.ts

```
export function invScope(args: {
  region: RegionAtom;
  init: RegionAtom;
}): Result<Artifact, JudgmentRefusal>
```

construction — ts/tests/spec-native.test.ts

```
| s.unwrap(j.invScope({ region: unitBox, init: j.box([[Q.of(1, 4), Q.of(1, 2)]] )})),
```

**Rust** mtk\_catalogue::judgment::QInvScope::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
| pub fn new(region: RegionAtom, init: RegionAtom) -> Self
```

construction — crates/mtk-catalogue/tests/roundtrip\_spec.rs

```
| let inv = QInvScope::new(
|   unit_box(),
|   RegionAtom::Box(IntervalBox(vec![Interval::new(q(1, 4), q(1, 2)).unwrap()])),
| );
```

## 14.10.9 QMorse: the global stratum

### Definition

$$\text{QMorse} : [\text{graph} : \text{MorseGraph}, \rho : \text{VertexRegion}^*, \text{arena} : \text{Arena}] \quad \mathcal{M} \models_D \text{Morse}(G, \rho)$$

Non-initialized, whole-system qualitative structure: a certified Morse graph with per-vertex readout regions. It is listed in this catalogue because a complete spec-language inventory must say where the non-formula-shaped claims live: the formula language and the global stratum share the region vocabulary and nothing else, and the  $D$  subscript marks the different satisfaction relation. The row asserts the graph and readouts against a declared *arena* — the grid complex the claim is read on; a discharged claim's arena is its lattice's, tied by a stated equation between hash-consed values (the tie is deliberately syntactic — semantic region equality is geometry the certificate does not owe). Acyclicity is the checker's to confirm, never this row's to assert, and the payload refuses out-of-range edge endpoints and vertex indices with the geometry named. Sub-logic: the Morse discharge and product rules of chapter 15, which carry the deepest mechanized ledger in the stack.

*Witness:* the Morse-graph certificate family across the corpus, up to certified graphs at the several-hundred-node scale.

### API

**TypeScript** judgment.morse

signature — ts/src/judgment.ts

```
| export function morse(args: {
|   vertices: number;
|   edges: ReadonlyArray<MorseEdge>;
|   rho: ReadonlyArray<VertexRegion>;
| }): Result<Artifact, JudgmentRefusal>
```

construction — ts/tests/spec-native.test.ts

```
| s.unwrap(
|   j.morse({
|     vertices: 2,
|     edges: [{ src: 0, dst: 1 }],
|     rho: [
|       { vertex: 0, region: phi },
|       { vertex: 1, region: s.TRUE },
|     ],
|   }),
| ),
```

**Rust** `mtk_catalogue::judgment::QMorse::new`

signature — `crates/mtk-catalogue/src/judgment/kinds.rs`

```
pub fn new(graph: MorseGraph, rho: Vec<VertexRegion>) -> Result<Self, Refusal>
```

construction — `crates/mtk-catalogue/tests/roundtrip_spec.rs`

```
let morse = QMorse::new(
  MorseGraph {
    vertices: 2,
    edges: vec![MorseEdge { src: 0, dst: 1 }],
  },
  vec![
    VertexRegion {
      vertex: 0,
      region: StatePred::poly_le(q(0, 1), Poly::var(0, 1).unwrap()),
    },
    VertexRegion {
      vertex: 1,
      region: StatePred::True,
    },
  ],
)
.unwrap();
```

#### 14.10.10 QWireCert: wiring certification

##### Definition

$$\text{QWireCert} : [w : \text{Wiring}, \text{premises} : \text{Spec}^*, \text{out} : \text{Spec}, \kappa : \text{Slack}]$$

The wiring  $w$  is certified for  $(\text{spec}_i) \Rightarrow \text{spec}_{\text{out}}$  with slack  $\kappa$  in the  $\mathcal{K}_{\infty}^0$  class. The premise list is positional against the wiring's inner-system order; lockstep with a consuming composition node's components is record-level conformance. Sub-logic: discharged from proof leaves for the two condition families of the composition calculus (mechanism certification; wiring-lens certification) [37], per region;  $\mathcal{K}_{\infty}$ -membership rows are proof-dischargeable; consumed by the wire-composition rule. The class membership and slack algebra are proven; the payload here freezes the API shape while the row's upstream schema staging follows the system-side work — stated so the reader knows which part is mathematics and which part is plumbing.

*Witness:* the assume–guarantee worked examples of chapter 15.

##### API

**TypeScript** `judgment.wireCert`

signature — `ts/src/judgment.ts`

```
export function wireCert(args: {
  wiring: WiringRef;
  premises: ReadonlyArray<SpecRef>;
  conclusion: SpecRef;
  gain: Poly;
}): Result<Artifact, JudgmentRefusal>
```

construction — `ts/tests/spec-native.test.ts`

```
s.unwrap(
  j.wireCert({
    wiring: j.wiringRef("w-loop"),
    premises: [j.specRef("inner-a"), j.specRef("inner-b")],

    gain: s.unwrap(s.poly([ { expts: [1], coeff: 0.of(1, 2) } ])),
  }),
),
```

**Rust** `mtk_catalogue::judgment::QWireCert::new`

signature — `crates/mtk-catalogue/src/judgment/kinds.rs`

```
pub fn new(
    wiring: WiringRef,
    premises: Vec<SpecRef>,
    conclusion: SpecRef,
    slack: Slack,
) -> Self
```

construction — `crates/mtk-catalogue/tests/roundtrip_spec.rs`

```
let wire_cert = QWireCert::new(
    WiringRef("w-loop".into()),
    vec![SpecRef("inner-a".into()), SpecRef("inner-b".into())],
    SpecRef("outer".into()),
    Slack {
        gain: Poly::new(vec![(vec![1u32], q(1, 2))]).unwrap(),
    },
);
```

### 14.10.11 QDist: distance judgments

#### Definition

$$\text{QDist}[d](A, B) \leq \varepsilon \quad d : \text{a declared distance functor (registry entry)}, \varepsilon \in \mathbb{Q}_{\geq 0}$$

The declared distance functor — a registry entry naming subject sort, symmetry flag, licensed rules, and observable meaning — between two subjects (system manifests, distribution snapshots, or definite descriptions with their well-formedness licenses) is at most exact-rational  $\varepsilon$ . Judgment-primary by design: triangle, weakening, and symmetry-per-flag are judgment-level admissibles, while the discharge rules are their own catalogue entries — coupling-witnessed drift, contraction-witnessed fixed-point balls, and the transport cells that degrade a judgment across an approximate simulation with the  $n\varepsilon$  compounding law made explicit. *Schema status*: chartered design — this kind's row species is not yet part of the normative row schema (`theories/Qtsl.geolog`); it enters with its discharge lanes, and until then the entry stands as the registry slot for the demand.

*Witness*: the coupling and contraction fixture families; the finite-kernel transport tier.

#### API

##### TypeScript `judgment.dist`

signature — `ts/src/judgment.ts`

```
export function dist(args: {
    functor: string;
    a: DistSubject;
    b: DistSubject;
    eps: QLike;
}): Result<Artifact, JudgmentRefusal>
```

construction — `ts/tests/spec-native.test.ts`

```
s.unwrap(
    j.dist({
        functor: "wasserstein-1",
        a: { kind: "manifest", sys: j.sysRef("sys-a") },
        b: { kind: "snapshot", locator: "snap-7" },
        eps: Q.of(1, 100),
    }),
),
```

**Rust** `mtk_catalogue::judgment::QDist::new`

signature — `crates/mtk-catalogue/src/judgment/kinds.rs`

```
pub fn new(
    functor: impl Into<String>,
    a: DistSubject,
    b: DistSubject,
    eps: WitRat,
) -> Result<Self, Refusal>
```

construction — `crates/mtk-catalogue/tests/roundtrip_spec.rs`

```
let dist = QDist::new(
    "wasserstein-1",
    DistSubject::Manifest(SysRef("sys-a".into())),
    DistSubject::Snapshot("snap-7".into()),
    q(1, 100),
)
.unwrap();
```

### 14.10.12 The existence family: QZeroExists, QEquilibriumExists, QFixedPointExists

#### Definition

$$\text{QZeroExists} : [g : \text{Poly}^m, \text{cell} : \text{QRegionAtom}] \quad \exists x \in \text{cell} : g(x) = 0$$

with the equilibrium and fixed-point members reading the same shape over a drift field and a map ( $g = F - \text{id}$ , tied by an elaboration recompute downstream).

Poincaré–Miranda member claims: a zero, an equilibrium, a fixed point, *in a cell*. Existence only — nothing in this family concludes uniqueness, count, or non-existence; that refusal boundary is the family’s design. In this edition the cell is a box atom and the subject is equidimensional ( $m$  components over an  $m$ -dimensional cell), refused otherwise with the geometry named. Sub-logic: the shared face-sign battery (rule + pinned oracle), and a derived rule reading an inward invariance box as an equilibrium witness.

*Witness*: the face-sign battery fixtures; the equilibrium readouts of the Morse–stratum examples.

#### API

**TypeScript** `judgment.zeroExists / equilibriumExists / fixedPointExists`

signature — `ts/src/judgment.ts`

```
export function zeroExists(args: {
    g: ReadonlyArray<Poly>;
    cell: RegionAtom;
}): Result<Artifact, JudgmentRefusal>

export function equilibriumExists(args: {
    field: ReadonlyArray<Poly>;
    cell: RegionAtom;
}): Result<Artifact, JudgmentRefusal>

export function fixedPointExists(args: {
    map: ReadonlyArray<Poly>;
    cell: RegionAtom;
}): Result<Artifact, JudgmentRefusal>
```

construction — `ts/tests/spec-native.test.ts`

```
s.unwrap(j.zeroExists({ g: g1, cell: unitBox })),
```

The equilibrium and fixed-point members construct beside it in the same test.

**Rust** `mtk_catalogue::judgment::{QZeroExists, QEquilibriumExists, QFixedPointExists}::new`

signature — `crates/mtk-catalogue/src/judgment/kinds.rs`

```
pub fn new(g: Vec<Poly>, cell: RegionAtom) -> Result<Self, Refusal>

pub fn new(field: Vec<Poly>, cell: RegionAtom) -> Result<Self, Refusal>

pub fn new(map: Vec<Poly>, cell: RegionAtom) -> Result<Self, Refusal>
```

construction — `crates/mtk-catalogue/tests/roundtrip_spec.rs`

```
let zero = QZeroExists::new(gl(), unit_box()).unwrap();
```

The equilibrium and fixed-point members construct beside it in the same test.

### 14.10.13 QSim: exact simulation

#### Definition

$\text{QSim} : [\text{src} : \text{System}, \text{dst} : \text{System}, \sigma : (\mathbb{N} \times \text{Mode} \times \text{Poly})^*] \quad \sigma : S \rightarrow S' \text{ an exact simulation map}$

The refinement preorder, one-sided by design:  $\sigma$  carries the finer system onto the coarser, and simulations compose. The map is stored as flat (coordinate, mode, polynomial) triples — one polynomial per destination coordinate per source mode, the mode cited as an entity rather than by name string, so a piece citing a nonexistent mode is unrepresentable rather than a silent key mismatch. The producer payload carries the same content mode-indexed — the outer list ranges over the source's modes, each inner list is that mode's destination coordinates — matching the transport builder's convention, refusing an empty mode roster and empty per-mode maps. Sub-logic: discharge at the strict tier (compatibility squares as proof leaves plus a mode-coverage walk) and the kernel tier (intertwining of kernels, machine-checked at its pushforward lemma); consumed by the simulation-transport rule, whose simulation premise is an ordinary premise of this kind — no hypothesis asterisk. The approximate  $(\sigma, \varepsilon)$  class deliberately concludes QDist, never this kind: exactness is what makes transport lossless, and blurring the two sorts would launder approximation through an exact-looking judgment.

*Witness:* the simulation-transport worked examples; the LunarLander tick-semantics pair is carried by this transport.

#### API

**TypeScript** `judgment.sim`

signature — `ts/src/judgment.ts`

```
export function sim(args: {
  sigma: ReadonlyArray<ReadonlyArray<Poly>>;
  from: SysRef;
  to: SysRef;
}): Result<Artifact, JudgmentRefusal>
```

construction — `ts/tests/spec-native.test.ts`

```
s.unwrap(
  j.sim({
    // one mode, one destination coordinate
    sigma: [[s.unwrap(s.polyVar(0, 1))]],
    from: j.sysRef("fine"),
    to: j.sysRef("coarse"),
  }),
),
```

**Rust** `mtk_catalogue::judgment::QSim::new`

signature — `crates/mtk-catalogue/src/judgment/kinds.rs`

```
| pub fn new(sigma: Vec<Vec<Poly>>, from: SysRef, to: SysRef) -> Result<Self, Refusal>
```

construction — `crates/mtk-catalogue/tests/roundtrip_spec.rs`

```
| let sim = QSim::new(
|   vec![vec![Poly::var(0, 1).unwrap()]], // one mode, one coordinate
|   SysRef("fine".into()),
|   SysRef("coarse".into()),
| )
| .unwrap();
```

#### 14.10.14 QFlatEq: flattening

##### Definition

$$\text{QFlatEq} : [\text{sys} : \text{System}, \text{flat} : \text{Manifest}] \quad \text{flat} = \text{flatten}(\text{sys})$$

The monolithic manifest is the flattening of the composite. Sub-logic: one oracle-shaped discharge (the substitution and guard-product recompute, registry-pinned, refusing loudly when unpinned), with the shared-carrier and binary-wiring confinements as refusal boundaries — completeness costs, never soundness hypotheses: what the oracle cannot flatten it refuses to speak about, rather than asserting under an assumption. Consumed by the flattening substitution rule. The measurable-tier witness (the parallel-composition law) is machine-checked.

*Witness:* the flattening fixtures of the composition suite.

##### API

**TypeScript** `judgment.flatEq`

signature — `ts/src/judgment.ts`

```
| export function flatEq(args: {
|   composite: SysRef;
|   flat: SysRef;
| }): Result<Artifact, JudgmentRefusal>
```

construction — `ts/tests/spec-native.test.ts`

```
| s.unwrap(j.flatEq({ composite: j.sysRef("comp"), flat: j.sysRef("mono") })),
```

**Rust** `mtk_catalogue::judgment::QFlatEq::new`

signature — `crates/mtk-catalogue/src/judgment/kinds.rs`

```
| pub fn new(composite: SysRef, flat: SysRef) -> Self
```

construction — `crates/mtk-catalogue/tests/roundtrip_spec.rs`

```
| let flat = QFlatEq::new(SysRef("comp".into()), SysRef("mono".into()));
```

#### 14.10.15 QAggScope: aggregate scope

##### Definition

$$\text{QAggScope} : [N : \text{System}, \text{aggdim} : \mathbb{N}, K : \text{PolytopeRow}^*, \text{stop} : \{\text{reachable}, \text{stopped}\}]$$

The aggregate image of every in-scope reachable marking of the net  $N$  lies in the polytope  $K$ , under the declared scope semantics. Reachability is composition-unstable (so not chase) and semantic (so not oracle) — which is why this is a judgment kind with rule discharge: the three confinement routes (cite an invariance-scope row; exit-guard structure, by oracle walk over guard rows; stopped semantics, by declared flag with a conformance tie) each conclude it, alongside P-invariant conservation certificates ( $y \cdot C = 0$ , exact-rational, witness carried) and capacity rows. Consumed by the aggregation-reduction rule as an ordinary premise. *Schema status*: designed, not yet rows — the aggregation-reduction node's row kits are in the normative schema; the scope kind's own row species joins them when its rows land.

*Witness*: the structurally bounded net families of the aggregation suite.

## API

### TypeScript judgment.aggScope

signature — ts/src/judgment.ts

```
export function aggScope(args: {
  net: SysRef;
  aggDim: number;
  polytope: ReadonlyArray<{ coeffs: ReadonlyArray<QLike>; ub: QLike }>;
  stop: ScopeSemantics;
}): Result<Artifact, JudgmentRefusal>
```

construction — ts/tests/spec-native.test.ts

```
s.unwrap(
  j.aggScope({
    net: j.sysRef("net-a"),
    aggDim: 2,
    polytope: [{ coeffs: [1n, 1n], ub: 10n }],
    stop: "reachable",
  }),
),
```

### Rust mtk\_catalogue::judgment::QAggScope::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
pub fn new(
  net: SysRef,
  agg_dim: usize,
  polytope: Vec<PolytopeRow>,
  stop: ScopeSemantics,
) -> Result<Self, Refusal>
```

construction — crates/mtk-catalogue/tests/roundtrip\_spec.rs

```
let agg = QAggScope::new(
  SysRef("net-a".into()),
  2,
  vec![PolytopeRow {
    coeffs: vec![q(1, 1), q(1, 1)],
    ub: q(10, 1),
  }],
  ScopeSemantics::Reachable,
)
.unwrap();
```

## 14.10.16 QStateFinite: a classification judgment

### Definition

$\text{QStateFinite} : [\text{sys} : \text{System}]$     the subject's state type is finite

A *classification* judgment: a class membership of the rule’s subject, not a per-application fact. Sub-logic: chase-derivable by structural refinement over the state-type formers (enumerations are finite; finite products of finite factors are finite; nesting inherits; the tensor former derives nothing, a deliberate negative), with a decidable oracle as fallback. Consumed where a discharge rule needs finiteness as a premise (the coupling-drift finite tier), which retires a side-condition asterisk into an ordinary premise; a future countable-tier proof targets a weaker classification, display untouched. *Schema status*: designed, not yet rows in the normative schema; the classification enters with its chase-refinement family.

*Witness*: the finite-tier coupling fixtures.

## API

### TypeScript judgment.stateFinite

signature — ts/src/judgment.ts

```
export function stateFinite(args: { sys: SysRef }): Result<
  Artifact,
  JudgmentRefusal
>
```

construction — ts/tests/spec-native.test.ts

```
s.unwrap(j.stateFinite({ sys: j.sysRef("sys-a") })),
```

### Rust mtk\_catalogue::judgment::QStateFinite::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
pub fn new(sys: SysRef) -> Self
```

construction — crates/mtk-catalogue/tests/roundtrip\_spec.rs

```
let fin = QStateFinite::new(SysRef("sys-a".into()));
```

## 14.10.17 QLinGrowth: a growth-class judgment

### Definition

$$\text{QLinGrowth} : [f : \text{Poly}^*, a, b : \mathbb{Q}_{\geq 0}, \text{scope} : \text{Box}] \quad \|f(x)\| \leq a\|x\| + b \text{ on the scope}$$

Membership in the linear-growth class with the *constants carried in the judgment*, so downstream cells consume  $(a, b)$  arithmetically rather than a membership bit. The kind is load-bearing because the fence it polices is provably sharp: the transport law it feeds is *false* outside the fragment (the  $n\varepsilon$  compounding of the distance-transport cell is sharp without a contraction row), so growth control must arrive as evidence, not assumption. Sub-logic: certificate-carrying — affine-envelope and Bernstein rows discharge it for polynomial drifts; composition and weakening admissibles do constant arithmetic.

*Witness*: the distance-transport pushforward cells’ premise rows.

## API

### TypeScript judgment.linGrowth

signature — ts/src/judgment.ts

```
export function linGrowth(args: {
  f: ReadonlyArray<Poly>;
  a: QLike;
  b: QLike;
  scope: RegionAtom;
}): Result<Artifact, JudgmentRefusal>
```

construction — ts/tests/spec-native.test.ts

```
| s.unwrap(  
|   j.linGrowth({ f: g1, a: 2n, b: Q.of(1, 2), scope: unitBox })),  
| ),
```

**Rust** mtk\_catalogue::judgment::QLinGrowth::new

signature — crates/mtk-catalogue/src/judgment/kinds.rs

```
| pub fn new(f: Vec<Poly>, a: WitRat, b: WitRat, scope: RegionAtom) -> Result<Self, Refusal>
```

construction — crates/mtk-catalogue/tests/roundtrip\_spec.rs

```
| let growth = QLinGrowth::new(g1(), q(2, 1), q(1, 2), unit_box()).unwrap();
```

### 14.10.18 The attitude blend: SHurwiczGE and SHurwiczLE (not a judgment kind)

#### Formation

$$\frac{\alpha \in \mathbb{Q} \quad 0 \leq \alpha \leq 1 \quad B \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{SHurwiczGE}(\alpha, B, R) \text{ AttitudeSpec}} \text{SHURWICZGE}$$

$$\frac{\alpha \in \mathbb{Q} \quad 0 \leq \alpha \leq 1 \quad B \in \mathbb{Q} \quad R \text{ PathObservable}}{\text{SHurwiczLE}(\alpha, B, R) \text{ AttitudeSpec}} \text{SHURWICZLE}$$

Certification is pessimism; design exploration wants the other end too, and occasionally a weighted blend — the Hurwicz optimism–pessimism criterion, transposed. Where the credal reading leaves a *set* of values at a run-functional, the blend mixes the two envelope readings with a declared attitude weight:  $\alpha = 0$  is the pure worst case (SReturnGE’s floor face, exactly),  $\alpha = 1$  the pure best case (SReturnMayBeGE’s witness face, exactly), and an interior  $\alpha$  mixes the two envelopes *arithmetically* into one scalar before thresholding, in checker-recomputed rational arithmetic. The pair therefore fits *neither* cap face, which is why it has its own sort instead of a mis-declared face — and the contrast with the record deserves its precise statement, because a specification is not envelope-pure either. A specification is *polarized*: every component carries a declared face, so its compiled verdict is truth-functional over per-component single-envelope discharges, monotone separately-per-slot with fixed sign, and verdict-mixing commutes with composition. The interior blend’s scalar has no sign in the refinement order — it mixes a quantity that shrinks under new admitted laws with one that grows — and it fails the marginal-extension tower property and equivalence with any single envelope bound (exact-rational countermodels are kernel-checked, both faces). In one line: **a Spec mixes verdicts; an attitude mixes envelopes** — and envelope-mixing is root-only, which is exactly where the record does its own mixing anyway.

Root-only-ness is now *type-level* — the fence-to-type upgrade of the theory revision: the pair concludes its own small cap sort, whose only consumer is the record’s score slot (spec\_score, section 14.3) — no connective, path former, or atom takes an AttitudeSpec argument, so occurrence below a root is unrepresentable rather than oracle-rejected, and the earlier edition’s whole-tree typing clause for this former is retired. What has *not* changed is the judgment-side exclusion, and it is the design: no rule concludes an attitude claim and no judgment sort exists for one — admitting the interior blend into the derivation calculus would break the citation discipline everything else preserves. Evaluation decomposes into the two extreme passes — one floor certificate, one witness certificate — mixed once at the root, and a verdict renders as a *design score*, never a guarantee. Nothing is lost at the endpoints: a nested blend at  $\alpha \in \{0, 1\}$  has its canonical spelling in the sibling formers.

*Witness*: the attitude fixtures of the producer surface; the credal-stratum examples of the semantic universe chapter (chapter 9, the section on agreement and the attitude operator).

#### API

**TypeScript** spec.hurwiczGe / hurwiczLe

signature — ts/src/judgment.ts + ts/src/spec.ts

```

export function hurwiczGe(
  alpha: QLike,
  lo: QLike,
  ret: PathObservable,
): AttitudeSpec

export function hurwiczLe(
  alpha: QLike,
  hi: QLike,
  ret: PathObservable,
): AttitudeSpec

export function hurwiczQuery(args: {
  alpha: QLike;
  root: SpecRef;
}): Result<Artifact, JudgmentRefusal>

```

construction — ts/tests/spec-native.test.ts

```

const hurwicz = s.hurwiczGe(Q.of(1, 3), 2n, s.poSum(11, s.oChan(1)));

```

The root-level query row (judgment.hurwiczQuery) remains beside the component formers as the judgment-tour vehicle for the blend.

**Rust** mtk\_catalogue::spec::AttitudeSpec::{hurwicz\_ge, hurwicz\_le}

signature — crates/mtk-catalogue/src/judgment/kinds.rs + crates/mtk-catalogue/src/spec/formula.rs

```

pub fn hurwicz_ge(
  alpha: WitRat,
  lo: WitRat,
  ret: PathObservable,
) -> Result<AttitudeSpec, Refusal>

pub fn hurwicz_le(
  alpha: WitRat,
  hi: WitRat,
  ret: PathObservable,
) -> Result<AttitudeSpec, Refusal>

pub fn new(alpha: WitRat, root: SpecRef) -> Result<Self, Refusal>

```

construction — crates/mtk-catalogue/tests/golden\_spec.rs

```

let hurwicz = AttitudeSpec::hurwicz_ge(
  q(1, 3),
  q(2, 1),
  PathObservable::sum(11, StateObservable::chan(1)).unwrap(),
)
.unwrap();

```

The root-level query row (HurwiczQueryV0) remains beside the component formers as the judgment-tour vehicle for the blend.

## Rule Catalogue

---

This chapter is the reference manual of the proof theory, and it is generated, not written: it incorporates the literate rule catalogue in full, emitted mechanically from the same sources the calculus is built from — the hand-authored rule cells, the Lean 4 development (statements extracted by declaration name and bound by hash at emission), the verifier-receipt store, the HOL4 development, and the per-rule proof files. Every rule of the proof theory has its section: statement in Steele’s metanotation, its producer API in TypeScript and Rust, commentary, mechanized realizations, receipts, and a proof at textbook detail; the coverage dashboard up front is the catalogue’s honest map of what the assurance edifice does and does not yet cover. Bernstein Logic appears here as what it has become in the finished design: the core fragment of one catalogue, not a separate system.

Inside this chapter the catalogue keeps its own conventions: one rule per entry, each starting on a fresh page, under stable catalogue rule numbers (indices of the roster, not section numbers — they also appear as PDF bookmarks), its own references at the end, and the page geometry it was designed at.

**What this catalogue is.** The proof rules of the certificate calculus, in two strata sharing one page discipline. The base stratum is **Bernstein Logic** — a small proof calculus for certificates about polynomial facts over networks of rational-tensor-valued wires: sequents  $\Phi \vdash \Psi$  asserting that every admissible valuation of the wires satisfying the premise  $\Phi$  satisfies the conclusion  $\Psi$ , with all trusted arithmetic exact over  $\mathbb{Q}$ . Its rules appear here in three tiers — core rules (kernel semantic content), admissible rules (verified unpackings into core rules), and alias rules (verified single-application spellings) — together with the composition rules (PROMISE, SYZYGY, SMALLGAIN, SMALLGAINN, PRODUCTLATTICE), which are Bernstein Logic outright. Above the base stratum sit the **QTSL rules**: rules concluding satisfaction judgments of the quantitative temporal specification language — a system satisfies a specification built from the specification chapter's formers — through the battery rules (safety, deadline, until, and Streett acceptance), the judgment-structure and specification-surface rules, the Morse-topology rules, composition and aggregation, distance transport, and the stored-chain certificate species (eventual-absorption brackets and generator-form contraction tails, recomputed exactly over stored chain rows), supported by discharge kits and arithmetic leaves that remain ordinary Bernstein Logic sequents. QTSL premises bottom out in Bernstein Logic sequents, and both strata are designed for one exact-replay discipline: a *certificate* is an acyclic derivation graph (judgment premises may be shared) whose nodes carry enough payload that a small checker can replay each rule's side conditions by exact rational computation — no search, no optimization, no floating point in the trusted base. Where a rule's row and checker arm are enacted, the checker replays it; the coverage dashboard names, rule by rule, what is enacted and what is not. Producers (LP/SDP pipelines, abstract interpreters, hand constructions) do whatever clever thing *finds* the certificate; the checker only replays. The catalogue opens with a coverage dashboard — one row per rule, covered or not, mapping the current level of mechanized verification of soundness, honest absences included — then a synopsis parade of every rule, then the rules grouped by subject.

The validity judgment itself is not free-floating: it is kernel-checked to be the possibilistic face of the semantic universe's satisfaction judgment (chapter 9), at the sequent's exact valuation carrier — a sequent is semantically valid iff the upper probability of its conclusion's complement vanishes under the credal compile of its premise cylinder's possibilistic wall (semanticallyValid\_iff\_face, module SuFunctor.Plain.CheckerFace) — so each soundness theorem in this catalogue is, through that identification, a statement about the semantic universe's own judgment.

Each rule of the calculus gets one section here, carrying five ingredients. (i) The rule itself, typeset in Steele's Computer Science Metanotation [225], with prose on what the rule does, when a producer uses it, and why each hypothesis is there. (ii) The Lean 4 declarations that realize it — the payload structure, the soundness theorem, and (where a side condition's meaning must be visible) the checker definitions in full — extracted mechanically from the sources at every build of this catalogue and bound by hash, so quoted text cannot drift from the tree silently. (iii) Verifier receipts: attestations that named checking layers — elaboration, kernel replay by the official external checker, a hardened screen, and a decorrelated second kernel — accepted the *exact build* being quoted, identified by the SHA-256 of the compiled module; every layer is a program the reader can re-run over the quoted sources. (iv) The HOL4 statement where the independent HOL4 development carries one, and a loud, reasoned absence where it does not. (v) A proof at textbook detail: ordinary mathematics for core rules, explicit rewriting recipes for admissible rules, filled-in applications of the target rule for alias rules. Where a rule's certificate content is carried by the baked theory, the section additionally quotes the theory rows — payload schema, side-condition demand relations, well-formedness axioms — mechanically from the theory source at every build, so a renamed or removed row fails the build rather than drifting silently.

**The theory as source.** The normative home of the rules' certificate content is the baked theory pair, shipped as data in theories/ beside this book: theory BernsteinLogic (the base calculus's proof tower, from ground dtypes through hypernets, formulas, and judgments to the proof species) and theory Qtsl (one omnibus extension carrying the specification language, the System stratum, the flavored cell schemas, the certificate sections — judgment kinds, proof-node payloads, batteries, the verdict form — and the certificate-shape stratum). Where this catalogue's statements and the theory disagree, the theory is the authority. Not every catalogued rule has a baked row home: entries whose certificate content is out of scope of the current baked theory say so outright — the rule remains catalogued, tiered, and proved at its stated scope, and its schema realization is named as a successor rather than implied.

**The certificate-shape stratum.** One stratum of the baked theory types certificates *as artifacts* rather than as derivations, and its consumers are the battery rules of this catalogue, so it is documented here. A *nondeterminism axis* (NDAxis) is an entity — identity is the choice source — carrying a total binding time and extent: btStep (re-chosen at every step; the axis enters drift reads cellwise as a region axis, and no envelope object is ever materialized) or btRun (committed once per run), with extent ndEnum (an enumerated branch count) or ndParam (a box enclosure of a parametric domain). A *certificate family* (CertFam) declares its own axis roster (cert\_axis); its branch-key space is the product of its enumerated run-bound axes in position order, keys riding the ground Shape sort as natural tuples — the scalar certificate is the nullary case (one branch under the width-zero key, not a second sort). Two refusals shape the roster: a family may not split over a step-bound axis, and may not enumerate a parametric one. Per-branch positional bodies (cert\_body) carry the certificate functions; position semantics belongs to the consuming rule. The existential face's slot is the id-keyed *selection* (cert\_selection: a named branch plus a properness witness; cert\_sel\_cell refines a parametric

domain, zero cell rows reading as the whole domain) — selections are mandatory by default, waived only when every consuming conclusion is safety-only. The universal face's economies are branch-discharge rows: an emptiness certificate (`cert_branch_empty`, the one optional slot), grade domination (`cert_dominates`, irreflexive and acyclic), and progressive-revelation hand-off (`cert_handoff`, prefix agreement between branch certificates). The stratum's structural demand is counting and ground comparison — admission, never geometry — and its deliberate absences are testable negatives: no envelope slot (a demonic envelope is a consuming rule's cellwise reading of the step axes, never an interface object), no verdict rows (those live with the certificate sections that consume them), no checker-arm vocabulary, and no branch-key structure sort.

**Why trust a green cell.** A green receipt row reduces to three things a skeptical reader can check independently: the statement printed on the page (hash-bound to the source file it was extracted from); the SHA-256 of the compiled artefact the receipt names; and the checker layers the receipt credits — each layer an independently runnable program (elaboration, official kernel replay, a hardened screen, a decorrelated second kernel), so a green cell never asks for trust in this book or its receipt store: rebuild the module, re-run the checkers, and compare. Staleness is always visible — a receipt attesting an older build, a statement that moved since its proof was written, a missing ingredient each render as an *amber* badge, never as silence. Red is reserved for outright verification failure. The coverage dashboard below records, rule by rule, which ingredients exist and which do not; the empty cells are deliberate, and are meant to be read.

**Naming conventions.** Judgment kinds carry a Q prefix (`QSat`, `QRegionSat`, ...): they are the satisfaction-judgment ( $\models$ -side) sorts of the extension theory, and the prefix is their namespace. Rules that conclude a satisfaction judgment carry the same Q; derivation-side ( $\vdash$ ) leaf rules stay bare or carry P, and mathematical eponyms are never forced into descriptive molds. Rule names end in a species suffix where one applies: *-Battery* — a certificate kit concluding a region judgment; *-Discharge* — evidence concluding a named judgment kind; *-Compose* — transport across a composition axis, named by the axis; *-Alias* — a verified one-application spelling; *-Rewrite* — an equivalence-concluding rewrite. A few rules carry a former name (marked “né”) from earlier editions of this catalogue.

Rendered 2026-08-04 03:24 UTC · receipts consulted from the store (checker-layer attestations) · tree 59ea8bd0e

## Coverage dashboard

One table over every rule of the catalogue, whether or not this edition covers it yet: a coverage dashboard that maps the current level of actual mechanized verification of soundness, rule by rule. Each covered section joins its ingredients from their single sources of truth: the rule cell from the hand-authored rules source (the same file the two-column diff pages render), the Lean statements from the sources by declaration name at every render, the receipts from the store (cited at render, never re-run), the HOL4 statement from the HOL4 development or a reasoned absence, and the proof from its hand-authored file. Rules with no catalogue entry yet render as all-absent rows, loudly. Some rows carry a Lean column without a catalogue section yet: their soundness theorems exist in the mechanized development (two sibling Lean packages — the core calculus and an auxiliary measure-theoretic library — both statement-bound by the same hash machinery), while their proof and HOL columns remain marked absent until those sections are authored. A module whose build has no attestation yet shows its receipt layers as none: statements are source-bound, and receipt coverage arrives when the checking gate next runs over that package.

Legend — one row per catalogue rule (every rules-page row carrying a tier), ordered by tier class: core rules first, then admissible, then alias, then the edge-discipline glue; within a class, catalogue order. The small gray mark after each rule names its source page (BL = the Bernstein Logic pages — the core roster and the composition rules, which are Bernstein Logic outright; QTSL = the QTSL rule roster). Lean: ✓ statement bound and fresh; an *amber* checkmark marks statements bound and fresh but warranting the rule *conditionally* — where the condition is a single named profile or fragment, the superscript says which (✓<sup>DTMC</sup> = proven at the discrete-kernel profile; the model-class names are the System chapter's), and the generic ✓<sup>hyp</sup> marks a warrant resting on a bag of named side conditions (the named hypotheses live on the rule's own catalogue page); ~ module moved since bind (~<sup>hyp</sup> likewise, for a conditional-warrant row — flag and label survive staleness), ✗ statement changed since bind (stale — the page badges say where), — no Lean binding. Corr: ✓ a reviewer-certified correspondence dictionary (how the Lean statements interpret the displayed rule) is current against the displayed cell, the statement texts, and its own prose; ~ a dictionary exists but its certification predates a change on some side; — no dictionary yet. The correspondence claim is reviewer-grade, not machine-checked — its machine-checked successor supersedes it per rule as soundness statements over rules-as-data land. Receipt layers (build/replay/hardened/decorrelated): **green** = a current receipt covers it, **amber** = stale receipts only, **grey** = none. HOL4: ✓ ported, ∅ out of scope by design, — absent; HOL rcpt: **doc** = documentary citation (no receipt store yet). (An Isabelle column is hidden while the Isabelle development is empty; it returns with its first entry.) Amber throughout means stale or absent; red is reserved for an outright verification failure. Empty cells are deliberate: the table records, rule by rule, what the assurance edifice does not yet cover.

## 15.1 Rule Synopsis

Every rule of the catalogue at a glance: the rule as realized in the mechanized development, its name, and the page of its full entry. The closing entry, set off by a rule, is the assembly-level discipline the numbered rules feed.

|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |     |

## 15.2 Core Structural Rules

### Rule 1. Ax (core rule)

#### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *Ax*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{}{\Phi \vdash \Phi} \text{Ax}$$

Ax is the leaf of every derivation: it discharges a sequent whose conclusion is literally its premise,  $\Phi \vdash \Phi$ . A producer uses it wherever a derivation bottoms out at an assumption — the demonstration certificate cited under the comparator note below begins with an Ax node discharging its composite premise before a conjunction elimination extracts the region fact a Bernstein-cone closure consumes.

What the checker recomputes is one thing: that the premise and conclusion are the *same formula tree*, compared node for node — no normalization, no reassociation, no matching. Formulas here are ordered trees, so Ax does not close  $\Phi \vdash \Phi'$  for a logically equivalent but differently shaped  $\Phi'$ ; that is re-derived through the conjunction rules when needed.

The single hypothesis is load-bearing in the obvious, total way: drop the equality and the premise-free rule concludes any sequent at all —  $\top \vdash \perp$  is the sharpest instance. Notably absent are well-typedness side conditions, and their absence is correct: whatever satisfaction amounts to for  $\Phi$  — even a  $\Phi$  mentioning untyped wires or atoms that never evaluate — it sits on both sides of the turnstile. The proof section contrasts this with *EqREFL*, which concludes a freshly minted *atom* and therefore does need typing fields.

#### Lean statement

BernsteinLogic.Soundness . **sound\_ax**

statement bound

```
theorem sound_ax {H : Hypernet} {seq : Sequent}
  (h : seq.pre = seq.post) : seq.semanticallyValid H
```

**How to read the payload.** A certificate node for this rule carries an inhabitant of the following inductive: its proof-obligation fields (here, one equality of formulas) are the rule's entire side-condition surface, and the soundness lemma above takes exactly those fields as hypotheses. The six other structural sections' payloads read the same way — sub-derivations plus structural equalities, nothing else.

BernsteinLogic.Core.Catalogue . **PAXData**

statement bound

```
inductive PAXData : Hypernet → Sequent → Type where
| mk (H : Hypernet) (seq : Sequent)
  (preEqPost : seq.pre = seq.post) : PAXData H seq
```

#### Correspondence (Steele display ↔ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

- the judgment frame, shared by every structural dictionary below: a sequent is the pair of its premise and conclusion formulas, so a displayed judgment  $\Phi \vdash \Psi \mapsto \text{seq} : \text{Sequent}$  with `seq.pre`, `seq.post` the two sides, and asserting it  $\mapsto$  the goal `seq.semanticallyValid H` — at every admissible valuation of the ambient hypernet  $H$ , satisfaction of `seq.pre` implies satisfaction of `seq.post`.

- the display's single metavariable  $\Phi$ , appearing on both sides of the turnstile,  $\mapsto$  the sole hypothesis  $h : \text{seq.pre} = \text{seq.post}$  — sharing by field equation on one sequent binder, not by a shared metavariable: the statement quantifies over *all* sequents and consumes the identity as its only input.
- premise-freeness  $\mapsto$  silence: no other hypothesis exists;  $H$  and  $\text{seq}$  are arbitrary.
- the payload row `PAXData` (certified alongside) carries the same single tie as certificate data (`preEqPost`), so admission layer and soundness statement coincide exactly on this rule.

No width difference in either direction: one hypothesis, consumed by rewriting; nothing else is stated or needed.

## Lean verifier receipts

module `BernsteinLogic.Soundness`; bound build `a20d90e66c13...` (bound from receipt `a9c0e34d3e3c9c8c`, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

| receipt                       | minted               | layers             | status  |
|-------------------------------|----------------------|--------------------|---------|
| <code>a9c0e34d3e3c9c8c</code> | 2026-08-03T21:30:36Z | build+decorrelated | current |

21 further receipt(s) in the store attest superseded builds of this module and are omitted from this rendering.

module `BernsteinLogic.Core.Catalogue`; bound build `cbc92e976a1d...` (bound from receipt `5abdb3589707b5df`, 2026-08-03T21:30:33Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

| receipt                       | minted               | layers             | status  |
|-------------------------------|----------------------|--------------------|---------|
| <code>24804e66edba0bc9</code> | 2026-08-03T20:25:09Z | build+decorrelated | current |
| <code>5abdb3589707b5df</code> | 2026-08-03T21:30:33Z | build+decorrelated | current |

18 further receipt(s) in the store attest superseded builds of this module and are omitted from this rendering.

### gate-layer coverage of the bound build:

build (lake build (elaboration)) current

replay (leanchecker (official kernel replay)) stale only

hardened (safe\_verify (hardened screen)) stale only

decorrelated (lean4export + nanoda (decorrelated kernel)) current

comparator: exercised via the demonstration fixture the composite demonstration certificate (an axiom node, a conjunction elimination, a Bernstein-cone closure) runs as a fixture through the three-implementation comparator harness (compiled / kernel-interpreted / reference-interpreted), so this rule's node rides every execution path of that harness.

## HOL4 statement

theory `bern_fam_ax`, HOL4 development script `bern_fam_axScript.sml` script bound

### Definition `checkFam_ax_def`

```

Definition checkFam_ax_def:
  checkFam_ax (cols:columns) (ct:ctx) (i:num) ⇔
    case conclRef cols ct i of
    | NONE => F
    | SOME cj =>
      case poolTagAt cols ct cj of
      | NONE => F
      | SOME t =>
        if t ≠ (48:num) then F else
        case poolField cols ct cj 0 of
        | NONE => F
        | SOME preR =>
          case poolField cols ct cj 1 of
          | NONE => F

```

```

| SOME postR =>
  if preR = postR then T
  else
    case pv cols ct cj of
    | SOME (PJudg prew postw) =>
      (expandSph FTt prew = expandSph FTt postw)
    | _ => F
End

```

**Theorem famEq\_ax**

```

Theorem famEq_ax:
  wfColumns cols ct ∧ mkCtx cols = SOME ct ∧
  nodeCorr cols ct i (CertPf sq nd) ∧
  FST (THE (tagOf cols i)) ∈ {0}
  ⇒
  (checkFam_ax cols ct i ⇔ (sq.pre = sq.post))

```

**HOL verifier receipts**

**documentary** Documentary citations. Spine census: `bern_joins` GREEN under `hol-strict` (55 theorems, 0 offences, 208-theory ancestry including this theory), `checkJoins_eq_checkPf` verified verbatim in the built signature. The cited `famEq` lemma is the kernel-checked per-node reduction: under well-formed columns (`wfColumns/mkCtx/nodeCorr`) at wire tag 0, the columnar family check holds iff the node's sequent satisfies the rule's own side condition (`sq.pre = sq.post`). There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twin `sound_ax` (theory `bern_tr_soundstruct`: `hol-strict` clean, 9 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

**Proof**

Genre: core rule (tier 1) — an ordinary mathematical proof at Putnam-exam-solution detail. This section also fixes the semantic setting shared by the seven structural sections (`AX`, `WEAKEN`, `CUT`, `∧I`, `∧E`, `∨I`, `∨E`); the later six abbreviate it as “the `Ax` setting”.

**Setting (shared by the structural sections).** Fix a hypernet  $H$  — the ambient computation graph: typed wires, each declaring a tensor shape and a dtype, and primitive applications connecting them. A *valuation*  $\sigma$  assigns each typed wire a tensor of values from its declared value set;  $\sigma$  is *admissible* when every primitive application in  $H$  satisfies its semantic relation. A formula holds at  $\sigma$  by structural recursion: an atom  $t_1 \bowtie t_2$  holds when — and only when — both terms evaluate — exact rational arithmetic, wires read whole, evaluation failing on untyped wires, on shape-incompatible arithmetic, and on any  $\pm\infty$ -valued wire mention — to tensors compared entrywise under  $\bowtie$  (a rank-0 side broadcasts; incompatible shapes never hold), so an atom either of whose terms fails to evaluate does not hold; a region atom holds when its term evaluates to a rational point of the named region;  $\Phi_1 \wedge \Phi_2$  holds when both conjuncts hold,  $\Phi_1 \vee \Phi_2$  when at least one disjunct holds,  $\top$  always,  $\perp$  never. A sequent  $\Phi \vdash \Psi$  is *semantically valid* over  $H$  when every admissible  $\sigma$  satisfying  $\Phi$  satisfies  $\Psi$ .

Two facts frame all seven structural proofs. First, formulas are *ordered trees*:  $\wedge$  and  $\vee$  are binary constructors, and every side condition of a structural rule is an identity of trees, checked structurally — no normalization, no reassociation, no commuting. Wherever a proof below “rewrites by” a payload field, it is replacing a formula by itself. Second, none of the seven proofs consumes admissibility: each threads it, unexamined, to its sub-derivations, so the structural fragment is sound over *arbitrary* valuations — premise and conclusion validity both read over all valuations, admissible or not — and the admissibility hypothesis rides along only because the validity statement quantifies over it. Where a counterexample is claimed in these sections, read it over the one-wire hypernet ( $w$  rational, rank-0, no applications): there every valuation is admissible, so an unsound conclusion genuinely falsifies.

**Claim (sound\_ax).** The payload certifies one equality, `pre = post` (`preEqPost`); under it the premise-free rule concluding  $\Phi \vdash \Phi$  is sound.

**Theorem R1.1** (soundness of `Ax`). *If  $\text{seq.pre} = \text{seq.post}$ , then  $\text{seq}$  is semantically valid over every hypernet.*

*Proof.* One step. Let  $\sigma$  be an admissible valuation with  $\sigma \models \text{seq.pre}$ . The certified equality says `seq.post` is `seq.pre` — the same tree, not merely an equivalent formula — so  $\sigma \models \text{seq.post}$ .  $\square$

**Remark R1.2** (the one hypothesis is everything). `Ax` has no premises, so the payload equality is its entire content. Drop `preEqPost` and the degenerate rule concludes an arbitrary sequent; the sharpest instance is  $\top \vdash \perp$  — every valuation satisfies the premise and none the conclusion.

**Remark R1.3** (identity is free; reflexivity is not). `Ax` carries no well-typedness side conditions, and this is correct rather than an oversight:  $\Phi \vdash \Phi$  is valid even when  $\Phi$  mentions untyped wires or atoms that can never evaluate, because satisfaction — whatever

it turns out to be — sits on both sides of the turnstile. Contrast  $\text{EqREFL}$ , which concludes the *atom*  $t = t$  under an arbitrary premise and does need shape and finiteness fields: an atom is a claim about evaluation, and an ill-typed  $t$  never evaluates, so there the conclusion can fail at valuations the premise never constrained.  $\text{Ax}$  never crosses that line because it introduces no content.

*Remark R1.4* (structural identity, not logical equivalence). The checker compares the two formula trees node for node.  $\Phi \vdash \Phi'$  for a logically equivalent but differently shaped  $\Phi' \multimap B \wedge A$  against  $A \wedge B$ , say — is *not* an  $\text{Ax}$  instance; where needed it is re-derived through  $\wedge\text{E}$  and  $\wedge\text{I}$ . In the lattice reading of the structural fragment (developed at the  $\vee\text{E}$  section),  $\text{Ax}$  is reflexivity of the entailment order — the Gentzen-style leaf [87], discharged semantically rather than by proof search.

| proof step                   | formal anchor                                                                                                                                               |

## Rule 2. WEAKEN (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *Weaken*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash \Psi}{\Phi \wedge \chi \vdash \Psi} \text{WEAKEN}$$

WEAKEN moves a proven sequent under a larger set of assumptions: from  $\Phi \vdash \Psi$  to  $\Phi \wedge \chi \vdash \Psi$ . A producer reaches for it when contexts must be made to agree — the structural rules with two premises (CUT,  $\wedge$ I,  $\vee$ E) and the composition rule's containment check all compare premise trees structurally, so a sequent proven from fewer assumptions is weakened into the context the next node expects.

The checker recomputes two tree identities: the conclusion's premise is exactly the sub-derivation's premise conjoined *on the right* with the named conjunct  $\chi$  (one new  $\wedge$ -node — position is data, since formulas are ordered trees), and the conclusion is carried over unchanged. Naming  $\chi$  in the payload keeps this a comparison, never a search.

Each hypothesis earns its keep. Drop the premise identity and weakening could silently *replace* assumptions rather than extend them — the proof section's counterexample derives  $\top \vdash w \leq 0$  from the valid  $w \leq 0 \vdash w \leq 0$ . Drop the conclusion identity and the conclusion is free. Nothing at all is demanded of  $\chi$  itself: an unsatisfiable or ill-typed conjunct only makes the new premise harder to satisfy, which costs applicability, never soundness — the rule only discards information.

### Lean statement

BernsteinLogic.Soundness . **sound\_weaken**

statement bound

```
theorem sound_weaken {H : Hypernet} {seq premise : Sequent} {extra : Formula}
  (ih : premise.semanticallyValid H)
  (hpre : seq.pre = .and premise.pre extra)
  (hpost : seq.post = premise.post) : seq.semanticallyValid H
```

Payload, read as in the Ax section: a sub-derivation plus structural equalities, nothing else.

BernsteinLogic.Core.Catalogue . **PWeakenData**

statement bound

```

  (premise : Sequent) (premiseProof : ProofObject H premise)
  (extra : Formula)
  (preEq : seq.pre = .and premise.pre extra)
  (postEq : seq.post = premise.post)
  : PWeakenData H seq
```

### Correspondence (Steele display $\leftrightarrow$ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in Ax.

- the premise judgment  $\Phi \vdash \Psi \mapsto ih : \text{premise.semanticallyValid } H$  — in the proof-object recursion this hypothesis is the sub-derivation's induction hypothesis; the payload (`PWeakenData`, certified alongside) carries the sub-derivation itself as a `ProofObject` field beside the same two ties.
- $\Phi \mapsto \text{premise.pre}$ ;  $\Psi \mapsto \text{premise.post}$ ;  $\chi \mapsto$  the binder `extra : Formula`, of which nothing is demanded.

- conclusion  $\Phi \wedge \chi \vdash \Psi \mapsto$  the goal under  $\text{hpre} : \text{seq.pre} = .$  and  $\text{premise.pre extra}$  — the displayed conjunction in the displayed order ( $\Phi$  left,  $\chi$  right; formulas are ordered trees, so the position is part of the certified statement) — and  $\text{hpost} : \text{seq.post} = \text{premise.post}$ .

No width difference in either direction: every hypothesis is consumed, and the statement proves exactly the displayed rule at every hypernet and sequent.

## Lean verifier receipts

module BernsteinLogic.Soundness; bound build a20d90e66c13... (bound from receipt a9c0e34d3e3c9c8c, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

## HOL verifier receipts

**documentary** Documentary citations. Family validation: `bern_fam_resid` built GREEN with all ten `famEq` arms validated, `hol-strict` clean; spine census: `bern_joins` GREEN under `hol-strict` (55 theorems, 0 offences, 208-theory ancestry including this theory), `checkJoins_eq_checkPf` verified verbatim in the built signature. The cited `famEq` lemma is the kernel-checked per-node equivalence: under well-formed columns (`wfColumns/mkCtx/nodeCorr`) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twin `sound_weaken` (theory `bern_tr_soundstruct`: `hol-strict` clean, 9 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

## Proof

Genre: core rule (tier 1). Setting as in the `Ax` section: valuations, admissibility, entrywise atom satisfaction, semantic validity; counterexamples read over the one-wire hypernet.

**Claim (`sound_weaken`).** The payload supplies a premise sequent  $\Phi \vdash \Psi$  with its sub-derivation, the added conjunct  $\chi$  (extra), and two tree identities: the conclusion's premise is  $\Phi \wedge \chi$  (`preEq`) and its conclusion is  $\Psi$  (`postEq`). If  $\Phi \vdash \Psi$  is semantically valid, so is  $\Phi \wedge \chi \vdash \Psi$ .

**Theorem R2.1 (soundness of `WEAKEN`).** *Under `preEq` and `postEq`, semantic validity of the premise sequent implies semantic validity of the conclusion sequent, over every hypernet.*

*Proof.* Let  $\sigma$  be admissible with  $\sigma \models \text{seq.pre}$  — by `preEq`, the tree  $\Phi \wedge \chi$ .

*Step 1 (project).* The  $\wedge$ -clause of satisfaction is meta-conjunction, so  $\sigma \models \Phi$  and  $\sigma \models \chi$ ; keep the left component and discard the right — this rule's whole activity is licensed forgetting.

*Step 2 (apply the premise).* Premise validity at  $\sigma$  gives  $\sigma \models \Psi$ , which `postEq` pins as the conclusion's post. □

**Remark R2.2** (`preEq` forces extension, not replacement). The identity `seq.pre` =  $\Phi \wedge \chi$  makes the conclusion's premise contain the sub-derivation's premise *verbatim* as the left conjunct of one new  $\wedge$ -node, with the named  $\chi$  on the right. Drop it and “weakening” could *replace* the assumptions instead of extending them: from  $w \leq 0 \vdash w \leq 0$  (an `Ax` instance) conclude  $\top \vdash w \leq 0$  — false at  $\sigma(w) = 1$ . This context-swap family is the standard counterexample to every dropped `preEq` in the structural sections; we cite it from here on rather than restating it.

**Remark R2.3** (positional discipline).  $\chi$  arrives as the right child of a single new  $\wedge$ -node:  $\Phi \wedge \chi$ , never  $\chi \wedge \Phi$ , and never merged into  $\Phi$ 's own tree. Any further placement is  $\wedge E/\wedge I$  work. Naming  $\chi$  in the payload keeps the checker's comparison pure structure — one tree identity, no matching or search.

**Remark R2.4** ( $\chi$  is unconstrained, harmlessly). Like `Ax`, the rule carries no typing side conditions on what it touches:  $\chi$  may be unsatisfiable ( $\perp$ ), ill-typed, or mention untyped wires. At worst the conclusion's premise becomes harder or impossible to satisfy — vacuous validity, never unsoundness. Weakening only discards information; rules that must *evaluate* are where typing fields live.

**Remark R2.5** (monotonicity, locally and wholesale). In the lattice reading (the  $\vee E$  section), meet is a lower bound: the interpretation of  $\Phi \wedge \chi$  lies below that of  $\Phi$ , which lies below that of  $\Psi$ . `WEAKEN` is the one-step premise-monotonicity of the consequence relation; the composition rule's conjunct-wise premise-containment check (`Szygy's preContains`) is the same monotonicity used wholesale.

| proof step                       | formal anchor                                                                                                                                                               |

## Rule 3. CUT (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *Cut*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash \chi \quad \Phi \wedge \chi \vdash \Psi}{\Phi \vdash \Psi} \text{CUT}$$

CUT is the lemma-staging rule: prove  $\Phi \vdash \chi$  once, prove  $\Phi \wedge \chi \vdash \Psi$  under the enlarged context, conclude  $\Phi \vdash \Psi$ . A producer uses it to factor a certificate the way a paper factors a proof — a bound or region fact is established once and then consumed as an assumption downstream; iterated cuts stage a chain of such lemmas.

The checker recomputes four tree identities: the conclusion's premise and conclusion are inherited from the left and right sub-derivations respectively; the left sub-derivation concludes exactly the named cut formula  $\chi$ ; and the right sub-derivation's premise is exactly the left one's premise conjoined with  $\chi$  — the same context tree, verbatim. The payload must name  $\chi$  explicitly because the conclusion mentions it nowhere: CUT is the one structural rule whose certified content is invisible in its conclusion, so there is nothing to reconstruct it from.

The two interesting hypotheses fail independently, with near-twin counterexamples walked in the proof section: unshare the context and a fact proven under foreign assumptions leaks into the conclusion ( $\top \vdash w \leq 0$  from two individually valid premises); unmoor  $\chi$  from the left conclusion and the right premise consumes an assumption nobody earned (same false conclusion, different route). The proof also records why no cut-elimination enters anywhere: soundness of the rule is direct, and the checker never normalizes a proof.

### Lean statement

BernsteinLogic.Soundness . **sound\_cut**

statement bound

```
theorem sound_cut {H : Hypernet} {seq leftPremise rightPremise : Sequent}
  {cutFormula : Formula}
  (ihl : leftPremise.semanticallyValid H)
  (ihr : rightPremise.semanticallyValid H)
  (hpre : seq.pre = leftPremise.pre)
  (hpost : seq.post = rightPremise.post)
  (hcutL : leftPremise.post = cutFormula)
  (hcutR : rightPremise.pre = .and leftPremise.pre cutFormula) :
  seq.semanticallyValid H
```

Payload, read as in the Ax section: sub-derivations plus structural equalities, with the cut formula as explicit data.

BernsteinLogic.Core.Catalogue . **PCutData**

statement bound

  (preEq : seq.pre = leftPremise.pre)
  (postEq : seq.post = rightPremise.post)
  (cutLeft : leftPremise.post = cutFormula)
  (cutRight : rightPremise.pre = .and leftPremise.pre cutFormula)
  : PCutData H seq
```

### Correspondence (Steele display ↔ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber

until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in **AX**; sub-derivation premises as at **WEAKEN**.

- the two premise judgments  $\Phi \vdash \chi$  and  $\Phi \wedge \chi \vdash \Psi \mapsto \text{ihl} : \text{leftPremise.semanticallyValid} \text{ } H \text{ and } \text{ihR} : \text{rightPremise.semanticallyValid} \text{ } H$ .
- $\Phi \mapsto \text{leftPremise.pre}; \Psi \mapsto \text{rightPremise.post}; \chi \mapsto$  the binder `cutFormula`, tied to the left conclusion by `hcutL : leftPremise.post = cutFormula` — the explicit naming the commentary explains (the conclusion mentions  $\chi$  nowhere).
- the second premise's displayed context  $\Phi \wedge \chi \mapsto \text{hcutR} : \text{rightPremise.pre} = .\text{and leftPremise.pre cutFormula}$  — the same context tree verbatim, cut formula conjoined on the right.
- conclusion  $\Phi \vdash \Psi \mapsto$  the goal under `hpre : seq.pre = leftPremise.pre` and `hpost : seq.post = rightPremise.post`.

No width difference in either direction: the six hypotheses are exactly the display's two premises and four structural identities, each consumed.

## Lean verifier receipts

module `BernsteinLogic.Soundness`; bound build `a20d90e66c13...` (bound from receipt `a9c0e34d3e3c9c8c`, 2026-08-03T21:30:36Z). **HOL verifier receipts**

**documentary** Documentary citations. Family validation: `bern_fam_resid` built GREEN with all ten `famEq` arms validated, `hol-strict` clean; spine census: `bern_joins` GREEN under `hol-strict` (55 theorems, 0 offences, 208-theory ancestry including this theory), `checkJoins_eq_checkPf` verified verbatim in the built signature. The cited `famEq` lemma is the kernel-checked per-node equivalence: under well-formed columns (`wfColumns/mkCtx/nodeCorr`) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twin `sound_cut` (theory `bern_tr_soundstruct`: `hol-strict` clean, 9 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

**Proof**

Genre: core rule (tier 1). Setting as in the `Ax` section; counterexamples read over the one-wire hypernet.

**Claim (sound\_cut).** The payload supplies the cut formula  $\chi$  (`cutFormula`), a left premise  $\Phi \vdash \chi$  and a right premise  $\Phi \wedge \chi \vdash \Psi$  with their sub-derivations, and four tree identities: the conclusion's premise is the left premise's premise (`preEq`), its conclusion is the right premise's conclusion (`postEq`), the left premise concludes exactly  $\chi$  (`cutLeft`), and the right premise's premise is exactly  $\Phi \wedge \chi$  over the *same*  $\Phi$  (`cutRight`). If both premise sequents are semantically valid, so is  $\Phi \vdash \Psi$ .

**Theorem R3.1** (soundness of `CUT`). *Under the four payload identities, semantic validity of both premise sequents implies semantic validity of the conclusion, over every hypernet.*

*Proof.* Let  $\sigma$  be admissible with  $\sigma \models \Phi$ .

*Step 1 (earn the cut formula).* By `preEq`,  $\sigma$  satisfies the left premise's premise; left validity gives  $\sigma \models \chi$  (`cutLeft` identifies the left conclusion with  $\chi$ ).

*Step 2 (assemble the enlarged context).* The  $\wedge$ -clause of satisfaction is meta-conjunction, so the standing assumption and Step 1 give  $\sigma \models \Phi \wedge \chi$  — and by `cutRight` this tree is the right premise's premise.

*Step 3 (apply the right premise).* Right validity gives  $\sigma \models \Psi$ , pinned as the conclusion's post by `postEq`.  $\square$

**Remark R3.2** (context sharing is load-bearing). `cutRight` forces the right premise's context to be the left premise's context — the context-sharing (*additive*) format [94]. Allow the right context to be foreign, say  $\Phi' \wedge \chi$ , and cut breaks: take the left premise  $\top \vdash \top$  (an `Ax` instance) and the right premise  $(w \leq 0) \wedge \top \vdash w \leq 0$  (valid: satisfaction of the conjunction projects); the degenerate rule would conclude  $\top \vdash w \leq 0$  — false at  $\sigma(w) = 1$ .

**Remark R3.3** (`cutLeft` moors the cut formula). Keep the sharing but unmoor  $\chi$  from what the left premise actually proved, and the right premise may consume an assumption nobody earned: from the left premise  $\top \vdash \top$  and the right premise  $\top \wedge (w \leq 0) \vdash w \leq 0$  (valid, again by projection), the degenerate rule would conclude  $\top \vdash w \leq 0$ . The two counterexamples are deliberately near-twins: `cutRight` guards *whose context*, `cutLeft` guards *whose lemma*, and each fails independently. `preEq`'s removal admits the context-swap family (the `WEAKEN` section); `postEq`'s removal frees the conclusion outright.

**Remark R3.4** (the cut formula leaves no trace). The conclusion  $\Phi \vdash \Psi$  mentions  $\chi$  nowhere — the conclusion does not determine the certified content (a hiddenness `CUT` shares with  $\wedge$ 's discarded conjunct), so the payload names `cutFormula` explicitly. That is a design choice rather than a forced move — the checker could equally read  $\chi$  off the left premise's post — and the explicit field keeps the check local. The same invisibility is what the rule is *for*: certificate producers stage lemmas — prove a bound or region fact once, then continue under the enlarged context  $\Phi \wedge \chi$  — and iterated cuts stage a chain of them.

*Remark R3.5* (semantic cut costs nothing). Gentzen’s Hauptsatz [87] eliminates cut from derivations at, in general, non-elementary blow-up in proof size [191, 224]; nothing here needs it. The soundness argument is the three steps above, the checker never normalizes a proof, and the calculus keeps CUT as a first-class node because producers want staged lemmas, not cut-free normal forms. In the lattice reading: if  $x \leq m$  then  $x = x \sqcap m$ , so  $x \sqcap m \leq y$  gives  $x \leq y$  — transitivity worn as meet bookkeeping.

| proof step                       | formal anchor                                                                                            |
|----------------------------------|----------------------------------------------------------------------------------------------------------|
| Steps 1–3                        | sound_cut; payload PCutData (fields cutFormula, preEq, postEq, cutLeft, cutRight); wired as RuleData.cut |

## Rule 4. $\wedge I$ (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` —  $\wedge I$ . The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash \Psi_1 \quad \Phi \vdash \Psi_2}{\Phi \vdash \Psi_1 \wedge \Psi_2} \wedge I$$

$\wedge I$  pairs two conclusions proven from the *same* assumptions: from  $\Phi \vdash \Psi_1$  and  $\Phi \vdash \Psi_2$ , conclude  $\Phi \vdash \Psi_1 \wedge \Psi_2$ . A producer uses it to assemble composite claims from separately established facts — two one-sided bounds into a two-sided one, the conjuncts a later node's premise-form expects — and, with  $\wedge E$ , to rebuild conjunction trees in the shape a structural comparison demands (the core never reassociates a conjunction on its own).

The checker recomputes three tree identities: the two sub-derivations' premises are the same tree, the conclusion inherits that premise, and the conclusion's post is one new  $\wedge$ -node with the left sub-derivation's conclusion on the left. Order is data:  $\Psi_1 \wedge \Psi_2$  and  $\Psi_2 \wedge \Psi_1$  are different conclusions, obtained by swapping which sub-derivation rides which payload slot.

The context-sharing identity is the load-bearing one. Drop it and the rule pairs facts earned under different assumptions, keeping only one set: from the valid  $\top \vdash \top$  and  $w \leq 0 \vdash w \leq 0$  it would conclude  $\top \vdash \top \wedge (w \leq 0)$ , false wherever  $w$  is positive. The proof section also records the structural observation the  $\vee E$  section turns into a theorem:  $\wedge I$  and  $\wedge E$  are the two directions of the universal property of meet, so the conjunction fragment adds nothing beyond the lattice structure of entailment.

### Lean statement

BernsteinLogic.Soundness . **sound\_andI**

statement bound

```
theorem sound_andI {H : Hypernet} {seq leftPremise rightPremise : Sequent}
  (ihl : leftPremise.semanticallyValid H)
  (ihr : rightPremise.semanticallyValid H)
  (hpreMatch : leftPremise.pre = rightPremise.pre)
  (hpre : seq.pre = leftPremise.pre)
  (hpost : seq.post = .and leftPremise.post rightPremise.post) :
  seq.semanticallyValid H
```

Payload, read as in the Ax section: sub-derivations plus structural equalities, nothing else.

BernsteinLogic.Core.Catalogue . **PAndIData**

statement bound

```
inductive PAndIData : Hypernet → Sequent → Type where
| mk (H : Hypernet) (seq : Sequent)
  (leftPremise : Sequent) (leftProof : ProofObject H leftPremise)
  (rightPremise : Sequent) (rightProof : ProofObject H rightPremise)
  (preMatch : leftPremise.pre = rightPremise.pre)
  (preEq : seq.pre = leftPremise.pre)
  (postEq : seq.post = .and leftPremise.post rightPremise.post)
  : PAndIData H seq
```

### Correspondence (Steele display $\leftrightarrow$ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in Ax; sub-derivation premises as at **WEAKEN**.

- the two premise judgments  $\mapsto$  `ihl/ihr` over the binders `leftPremise/rightPremise`.

- the display writes one context  $\Phi$  twice; the statement binds two sequents and demands  $\text{hpreMatch} : \text{leftPremise.pre} = \text{rightPremise.pre}$  — sharing by equation rather than by a common binder, the pattern of every two-premise rule on this page.
- $\Phi \mapsto \text{leftPremise.pre}$  (hence, through the match,  $\text{rightPremise.pre}$ );  $\Psi_1 \mapsto \text{leftPremise.post}$ ;  $\Psi_2 \mapsto \text{rightPremise.post}$ .
- conclusion  $\Phi \vdash \Psi_1 \wedge \Psi_2 \mapsto$  the goal under  $\text{hpre} : \text{seq.pre} = \text{leftPremise.pre}$  and  $\text{hpost} : \text{seq.post} = \text{rightPremise.post}$  — left sub-derivation on the left, as displayed.

No width difference in either direction; every hypothesis is consumed.

## Lean verifier receipts

module BernsteinLogic.Soundness; bound build a20d90e66c13... (bound from receipt a9c0e34d3e3c9c8c, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

```

## HOL verifier receipts

**documentary** Documentary citations. Family validation: `bern_fam_resid` built GREEN with all ten `famEq` arms validated, `hol-strict` clean; spine census: `bern_joins` GREEN under `hol-strict` (55 theorems, 0 offences, 208-theory ancestry including this theory), `checkJoins_eq_checkPf` verified verbatim in the built signature. The cited `famEq` lemma is the kernel-checked per-node equivalence: under well-formed columns (`wfColumns/mkCtx/nodeCorr`) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twin `sound_andI` (theory `bern_tr_soundstruct`: `hol-strict` clean, 9 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

## Proof

Genre: core rule (tier 1). Setting as in the `Ax` section; counterexamples read over the one-wire hypernet.

**Claim (`sound_andI`).** The payload supplies two premise sequents  $\Phi \vdash \Psi_1$  and  $\Phi \vdash \Psi_2$  with their sub-derivations and three tree identities: the two premises share one context (`preMatch`), the conclusion's premise is that context (`preEq`), and the conclusion's post is  $\Psi_1 \wedge \Psi_2$  with the left premise's conclusion as left conjunct (`postEq`). If both premise sequents are semantically valid, so is  $\Phi \vdash \Psi_1 \wedge \Psi_2$ .

**Theorem R4.1** (soundness of  $\wedge$ I). *Under the three payload identities, semantic validity of both premise sequents implies semantic validity of the conclusion, over every hypernet.*

*Proof.* Let  $\sigma$  be admissible with  $\sigma \models \Phi$ .

*Step 1 (left component).* By `preEq`,  $\sigma$  satisfies the left premise's premise; left validity gives  $\sigma \models \Psi_1$ .

*Step 2 (right component).* `preMatch` transports  $\sigma \models \Phi$  verbatim to the right premise's premise — the same tree, so the same satisfaction fact; right validity gives  $\sigma \models \Psi_2$ .

*Step 3 (pair).* The  $\wedge$ -clause of satisfaction is meta-conjunction, so  $\sigma \models \Psi_1 \wedge \Psi_2$ , pinned by `postEq`. □

**Remark R4.2** (`preMatch` is load-bearing). The rule may only pair conclusions drawn from the *same* assumptions — context sharing again, as at `CUT` [94]. Drop `preMatch` and take the left premise  $\top \vdash \top$  and the right premise  $w \leq 0 \vdash w \leq 0$  (both `Ax` instances): the degenerate rule concludes  $\top \vdash \top \wedge (w \leq 0)$  — false at  $\sigma(w) = 1$ , because the right conjunct was earned under an assumption the conclusion no longer carries. `preEq`'s removal admits the context-swap family (the `WEAKEN` section); `postEq`'s removal frees the conclusion outright.

**Remark R4.3** (order and association are data). `postEq` places the left premise's conclusion on the left of one new  $\wedge$ -node. The conjunction is an ordered tree: nothing in the core commutes or reassociates it, so  $\Psi_1 \wedge \Psi_2$  and  $\Psi_2 \wedge \Psi_1$  are different conclusions, each derivable from the same premises by choosing which sub-derivation rides which payload slot.

**Remark R4.4** (the meet adjunction, split across two rules). In the lattice reading,  $\wedge I$  is one direction of the universal property of meet —  $x \leq y$  and  $x \leq z$  iff  $x \leq y \sqcap z$  — and  $\wedge E$  is the other. Together the two rules say the  $\wedge$ -fragment of the calculus adds nothing beyond the lattice structure of entailment; the  $\vee E$  section makes this precise (and load-bearing) through a countermodel over exactly that structure. With  $\wedge E$  the pair is also computationally lossless at the formula-tree level: the two projections undo pairing, and pairing the two projections rebuilds the identical formula tree.

| proof step                       | formal anchor                                                                                                                                                            |

## Rule 5. $\wedge E$ (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` —  $\wedge E$ . The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash \Psi_1 \wedge \Psi_2}{\Phi \vdash \Psi_i} \wedge E$$

$\wedge E$  projects a conjunction: from  $\Phi \vdash \Psi_1 \wedge \Psi_2$ , conclude  $\Phi \vdash \Psi_i$ . A producer uses it to take composite facts apart — the demonstration certificate applies it right after its axiom leaf, extracting from a composite premise the region conjunct that the Bernstein-cone closure needs — and, with  $\wedge I$ , to reshape conjunction trees for the structural comparisons other rules perform.

The rule is realized as two constructors, one per side; the paper's index  $i \in \{1, 2\}$  is the constructor choice itself, so there is no unchecked side flag. The checker recomputes two tree identities: shared context, and that the sub-derivation's conclusion is exactly the conclusion's post conjoined with the *named* discarded conjunct — on the right for the left constructor, on the left for the right one. Naming the discarded conjunct in the payload makes the side condition a single comparison; the checker never searches a conjunction for the target, and a certificate claiming the wrong side simply fails the identity.

Dropping the conclusion identity frees the conclusion outright; dropping the context identity admits the context-swap counterexamples walked at **WEAKEN**. The projection itself needs no defence: discarding a conjunct only weakens a claim, and the proof section notes the pairing with  $\wedge I$  under which the fragment is lossless at the formula-tree level.

### Lean statement

BernsteinLogic.Soundness . **sound\_andE\_left**

statement bound

```
theorem sound_andE_left {H : Hypernet} {seq premise : Sequent} {other : Formula}
  (ih : premise.semanticallyValid H)
  (hpre : seq.pre = premise.pre)
  (hpost : premise.post = .and seq.post other) :
  seq.semanticallyValid H
```

BernsteinLogic.Soundness . **sound\_andE\_right**

statement bound

```
theorem sound_andE_right {H : Hypernet} {seq premise : Sequent} {other : Formula}
  (ih : premise.semanticallyValid H)
  (hpre : seq.pre = premise.pre)
  (hpost : premise.post = .and other seq.post) :
  seq.semanticallyValid H
```

Payload, read as in the **Ax** section: one constructor per projection, each a sub-derivation plus structural equalities with the discarded conjunct as explicit data.

BernsteinLogic.Core.Catalogue . **PAndEData**

statement bound

```
inductive PAndEData : Hypernet → Sequent → Type where
| left (H : Hypernet) (seq : Sequent)
  (premise : Sequent) (premiseProof : ProofObject H premise)
  (other : Formula)
  (preEq : seq.pre = premise.pre)
  (postEq : premise.post = .and seq.post other)
  : PAndEData H seq
| right (H : Hypernet) (seq : Sequent)
  (premise : Sequent) (premiseProof : ProofObject H premise)
  (other : Formula)
  (preEq : seq.pre = premise.pre)
  (postEq : premise.post = .and other seq.post)
  : PAndEData H seq
```

## Correspondence (Steele display $\leftrightarrow$ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in **Ax**; sub-derivation premise as at **WEAKEN**.

- the display's index  $i \in \{1, 2\} \mapsto$  the *choice of lemma*: `sound_andE_left` is  $i = 1$ , `sound_andE_right` is  $i = 2$ , mirroring the payload's two constructors — the side is a constructor choice, never an unchecked flag.
- premise judgment  $\Phi \vdash \Psi_1 \wedge \Psi_2 \mapsto$  `ih`, with the conjunction shape carried by `hpost`: in the left lemma `premise.post = .and seq.post other` — the surviving conjunct  $\Psi_i$  is the conclusion's own post field, and the discarded conjunct  $\Psi_{3-i} \mapsto$  the binder `other` (right lemma: mirrored, `.and other seq.post`).
- $\Phi \mapsto$  `premise.pre`, shared via `hpre : seq.pre = premise.pre`; conclusion  $\Phi \vdash \Psi_i \mapsto$  the goal `seq.semanticallyValid H`.

No width difference in either direction: the lemma pair covers exactly the displayed  $i$ -indexed family, and every hypothesis is consumed.

## Lean verifier receipts

module `BernsteinLogic.Soundness`; bound build `a20d90e66c13...` (bound from receipt `a9c0e34d3e3c9c8c`, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

```

**HOL verifier receipts**

[documentary](#) Documentary citations. Spine census: `bern_joins` GREEN under `hol-strict` (55 theorems, 0 offences, 208-theory ancestry including this theory), `checkJoins_eq_checkPf` verified verbatim in the built signature. The cited `famEq` lemma is the kernel-checked per-theory equivalence: under well-formed columns (`wfColumns/mkCtx/nodeCorr`) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twins `sound_andE_left` / `sound_andE_right` (theory `bern_tr_soundstruct`: `hol-strict` clean, 9 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified- fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

**Proof**

Genre: core rule (tier 1). Setting as in the `Ax` section; counterexamples read over the one-wire hypernet.

**Claim (`sound_andE_left` / `sound_andE_right`).** The rule is realized as two constructors, one per projection; the payload of either supplies a premise sequent with its sub-derivation, the *discarded* conjunct (*other*), and two tree identities: shared context (`preEq`) and, for the left constructor, that the premise's conclusion is `post ∧ other` — for the right, `other ∧ post` (`postEq`). If the premise sequent  $\Phi \vdash \Psi_1 \wedge \Psi_2$  is semantically valid, so is  $\Phi \vdash \Psi_i$ .

**Theorem R5.1** (soundness of  $\wedge E$ ). *Under the payload identities of either constructor, semantic validity of the premise sequent implies semantic validity of the conclusion, over every hypernet.*

*Proof.* Left constructor; the right is its mirror image.

*Step 1 (apply the premise).* Let  $\sigma$  be admissible with  $\sigma \models \Phi$ ; by `preEq` and premise validity,  $\sigma$  satisfies the premise’s conclusion.

*Step 2 (read it as a pair and project).* `postEq` says that conclusion is the tree `seq.post`  $\wedge$  other; the  $\wedge$ -clause of satisfaction is meta-conjunction, so  $\sigma$  satisfies both conjuncts. Keep the left one:  $\sigma \models \text{seq.post}$ .  $\square$

*Remark R5.2* (the discarded conjunct is named, so nothing is searched). Carrying other in the payload turns the side condition into one structural identity: the checker never hunts through the premise’s conclusion for an occurrence of the target — it compares two named trees. Orientation is checked by the same identity: a left-constructor certificate claiming the *right* conjunct fails `postEq` unless the two conjuncts happen to be the same tree, in which case the distinction is empty anyway.

*Remark R5.3* (the index is a constructor, not a flag). The paper’s  $i \in \{1, 2\}$  is realized as the choice between two constructors rather than an integer field — there is no unchecked side flag to corrupt, and each constructor’s soundness lemma is its own two-line proof. Dropping `postEq` in either frees the conclusion outright; dropping `preEq` admits the context-swap family (the `WEAKEN` section).

*Remark R5.4* (one-way information loss, two-way fragment). Projection discards its other irrecoverably — the conclusion carries no trace of it (compare `CUT`, whose conclusion hides the cut formula; here the forgetting is the visible point of the rule). Together with  $\wedge I$  the fragment is lossless at the formula-tree level: see the meet-adjunction remark in the  $\wedge I$  section. In the lattice reading these are `M3.andE_l_kit`/`M3.andE_r_kit`, the upper direction of meet’s universal property.

| proof step       | formal anchor                                                                                                                              |

## Rule 6. $\vee I$ (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` —  $\vee I$ . The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash \Psi_i}{\Phi \vdash \Psi_1 \vee \Psi_2} \vee I$$

$\vee I$  injects a proven conclusion into a disjunction: from  $\Phi \vdash \Psi_i$ , conclude  $\Phi \vdash \Psi_1 \vee \Psi_2$  — conclusion-side weakening, the mirror of  $\text{WEAKEN}$ 's premise side. A producer mostly reaches for it to make the branches of a disjunction elimination agree: each branch proves its own branch-specific fact and  $\vee I$ -injects it into the common disjunction the elimination's conclusion-matching check demands. The separation instance discussed at  $\vee E$  is the miniature — both of its branch derivations are an axiom node followed by one  $\vee I$  node.

Like  $\wedge E$ , the rule is realized as two constructors, one per side; the injected side is the constructor choice. The checker recomputes two tree identities: shared context, and that the conclusion's post is one new  $\vee$ -node with the sub-derivation's conclusion on the constructor's side and the *named* added disjunct on the other.

Nothing whatsoever is demanded of the added disjunct — it may be unsatisfiable, ill-typed, or mention untyped wires — because satisfaction of a disjunction demands only the witnessed side, and the satisfaction relation carries no typing side conditions of its own; typing enters the calculus only through rules that must evaluate. Dropping the conclusion identity frees the conclusion outright; dropping the context identity admits the context-swap family walked at  $\text{WEAKEN}$ .

### Lean statement

BernsteinLogic.Soundness . **sound\_orI\_left**

statement bound

```
theorem sound_orI_left {H : Hypernet} {seq premise : Sequent} {other : Formula}
  (ih : premise.semanticallyValid H)
  (hpre : seq.pre = premise.pre)
  (hpost : seq.post = .or premise.post other) :
  seq.semanticallyValid H
```

BernsteinLogic.Soundness . **sound\_orI\_right**

statement bound

```
theorem sound_orI_right {H : Hypernet} {seq premise : Sequent} {other : Formula}
  (ih : premise.semanticallyValid H)
  (hpre : seq.pre = premise.pre)
  (hpost : seq.post = .or other premise.post) :
  seq.semanticallyValid H
```

Payload, read as in the  $Ax$  section: one constructor per injection, each a sub-derivation plus structural equalities with the added disjunct as explicit data.

BernsteinLogic.Core.Catalogue . **P0rIData**

statement bound

```
inductive P0rIData : Hypernet → Sequent → Type where
| left (H : Hypernet) (seq : Sequent)
  (premise : Sequent) (premiseProof : ProofObject H premise)
  (other : Formula)
  (preEq : seq.pre = premise.pre)
  (postEq : seq.post = .or premise.post other)
  : P0rIData H seq
| right (H : Hypernet) (seq : Sequent)
  (premise : Sequent) (premiseProof : ProofObject H premise)
  (other : Formula)
  (preEq : seq.pre = premise.pre)
  (postEq : seq.post = .or other premise.post)
  : P0rIData H seq
```

## Correspondence (Steele display $\leftrightarrow$ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in **Ax**; sub-derivation premise as at **WEAKEN**.

- the display's index  $i \in \{1, 2\} \mapsto$  the choice of lemma, exactly as at  $\wedge E$ : **sound\_orI\_left** is  $i = 1$ , **sound\_orI\_right** is  $i = 2$ , mirroring the payload's two constructors.
- premise judgment  $\Phi \vdash \Psi_i \mapsto$  **ih**; the injected disjunct  $\Psi_i$  is **premise.post**, and the added disjunct  $\Psi_{3-i} \mapsto$  the binder **other**, of which nothing is demanded.
- conclusion  $\Phi \vdash \Psi_1 \vee \Psi_2 \mapsto$  the goal under **hpost**: in the left lemma **seq.post** = **.or premise.post other** (right lemma mirrored);  $\Phi \mapsto$  **premise.pre**, shared via **hpre**.

No width difference in either direction: the lemma pair covers exactly the displayed  $i$ -indexed family, and every hypothesis is consumed.

## Lean verifier receipts

module BernsteinLogic.Soundness; bound build a20d90e66c13... (bound from receipt a9c0e34d3e3c9c8c, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

| receipt          | minted               | layers             | status  |

**HOL verifier receipts**

**documentary** Documentary citations. Family validation: `bern_fam_resid` built GREEN with all ten `famEq` arms validated, `hol-strict` clean; spine census: `bern_joins` GREEN under `hol-strict` (55 theorems, 0 offences, 208-theory ancestry including this theory), `checkJoins_eq_checkPf` verified verbatim in the built signature. The cited `famEq` lemma is the kernel-checked per-node equivalence: under well-formed columns (`wfColumns/mkCtx/nodeCorr`) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twins `sound_orI_left` / `sound_orI_right` (theory `bern_tr_soundstruct`: `hol-strict` clean, 9 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified- fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

**Proof**

Genre: core rule (tier 1). Setting as in the `Ax` section; counterexamples read over the one-wire hypernet.

**Claim (`sound_orI_left` / `sound_orI_right`).** Two constructors, one per injection; the payload of either supplies a premise sequent  $\Phi \vdash \Psi_i$  with its sub-derivation, the *added* disjunct (*other*), and two tree identities: shared context (`preEq`) and, for the left constructor, that the conclusion's post is  $\Psi_i \vee \text{other}$  — for the right, *other*  $\vee \Psi_i$  (`postEq`). If the premise sequent is semantically valid, so is  $\Phi \vdash \Psi_1 \vee \Psi_2$ .

**Theorem R6.1** (soundness of  $\vee$ I). *Under the payload identities of either constructor, semantic validity of the premise sequent implies semantic validity of the conclusion, over every hypernet.*

*Proof.* Left constructor; the right is its mirror image.

*Step 1 (apply the premise).* Let  $\sigma$  be admissible with  $\sigma \models \Phi$ ; by `preEq` and premise validity,  $\sigma \models \Psi_i$ .

*Step 2 (inject).* The  $\vee$ -clause of satisfaction is meta-disjunction, and a disjunction is satisfied by satisfying either side; the witnessed side is  $\Psi_i$ , and `postEq` pins the conclusion's post as the tree  $\Psi_i \vee \text{other}$ .  $\square$

**Remark R6.2** (the added disjunct is wholly unconstrained). *other* may be unsatisfiable, ill-typed, or mention untyped wires; nothing is demanded of it, because satisfaction of a disjunction demands only the witnessed side and the satisfaction relation carries no typing side conditions of its own — typing enters the calculus only through rules that must evaluate.  $\vee$ I is conclusion-side weakening, the mirror of `WEAKEN`'s premise side: both discard strength, and discarding is always semantically safe. Dropping `postEq` frees the conclusion outright; dropping `preEq` admits the context-swap family (the `WEAKEN` section).

**Remark R6.3** (where a producer actually reaches for it). Mostly to make two branches agree: the branches of a disjunction elimination must conclude a *common* formula, so each branch  $\vee$ I-injects its own branch-specific conclusion into the shared disjunction. The separation instance quoted in the  $\vee$ E section is the miniature: both of its branch derivations are an `Ax` node followed by one  $\vee$ I node (left in one branch, right in the other).

*Remark R6.4* (lattice reading).  $x \leq y$  implies  $x \leq y \sqcup z$ : the upper-bound half of join’s universal property (`M3.orI_l_kit`/`M3.orI_r_kit`); the other half is exactly  $\vee E$ . The four  $\wedge/\vee$  rules are the meet and join adjunctions in full, which is the observation the  $\vee E$  section’s countermodel turns into a theorem about what the core *cannot* derive.

## Rule 7. $\vee E$ (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` —  $\vee E$ . The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi_1 \vdash \Psi \quad \Phi_2 \vdash \Psi}{\Phi_1 \vee \Phi_2 \vdash \Psi} \vee E$$

$\vee E$  is the calculus's only branching rule — case analysis: from  $\Phi_1 \vdash \Psi$  and  $\Phi_2 \vdash \Psi$ , conclude  $\Phi_1 \vee \Phi_2 \vdash \Psi$ . The disjunctions worth eliminating come from the hypernet's synthesized primitive facts — a cell indicator's finite case list, a rectifier's sign split — and a producer eliminates them by proving the goal once per case over the correspondingly strengthened premise.

The checker recomputes three tree identities: the two branch sub-derivations conclude the same formula, the conclusion's premise is exactly the  $\vee$ -node of the two branch premises, and the conclusion's post is the common branch conclusion. The conclusion-matching identity is the load-bearing one — drop it and a fact proven only in one branch escapes the case split (the proof section's counterexample); the premise identity's removal admits the context-swap family.

The essential caveat of this section, though, is the rule's *reach*: the quoted form eliminates a disjunction only when it is the *whole* premise, while in practice every eliminable disjunction arrives as a conjunct inside the premise — and the core provably cannot restructure its way there (distribution of  $\wedge$  over  $\vee$  is underivable; the proof section exhibits the mechanized lattice countermodel). The context-carrying generalization — same rule, plus a conjunct path addressing the disjunction inside the premise's  $\wedge$ -tree — is proven sound, proven to be a proper extension, and proven to collapse onto the quoted form at the identity path; the accompanying development treats it as the intended elimination rule, with the quoted plain form destined to become its boundary alias.

### Lean statement

BernsteinLogic.Soundness . **sound\_orE**

statement bound

```
theorem sound_orE {H : Hypernet} {seq leftPremise rightPremise : Sequent}
  (ihl : leftPremise.semanticallyValid H)
  (ihr : rightPremise.semanticallyValid H)
  (hpostMatch : leftPremise.post = rightPremise.post)
  (hpre : seq.pre = .or leftPremise.pre rightPremise.pre)
  (hpost : seq.post = leftPremise.post) :
  seq.semanticallyValid H
```

Payload of the plain form, read as in the Ax section: two branch sub-derivations plus structural equalities.

BernsteinLogic.Core.Catalogue . **P0rEData**

statement bound

```
inductive P0rEData : Hypernet → Sequent → Type where

/-! ## §A9 The metatheorem: derivability is lattice-sound

Over a hypernet with no typed wires, every derivable sequent satisfies  $\llbracket \text{pre} \rrbracket \leq \llbracket \text{post} \rrbracket$  in  $M_3$ . One case per rule of the catalogue; the propositional rules are the lattice axioms, equality elimination is the substitution invariance (its typing field forces both terms closed over an untyped hypernet), the region/arithmetic-closure rules are handled by their conclusion shapes or payload absurdities, and the empty-payload rules are vacuous. -/

```

## Correspondence (Steele display $\leftrightarrow$ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in Ax; sub-derivation premises as at WEAKEN. The displayed rule corresponds to sound\_orE:

- the branch judgments  $\Phi_1 \vdash \Psi$  and  $\Phi_2 \vdash \Psi \mapsto \text{ihl}/\text{ih}$ ; the shared conclusion  $\Psi$  is shared by equation,  $\text{hpostMatch} : \text{leftPremise.post} = \text{rightPremise.post}$  — the load-bearing identity the commentary singles out.
- $\Phi_1 \mapsto \text{leftPremise.pre}$ ;  $\Phi_2 \mapsto \text{rightPremise.pre}$ ; the conclusion's premise  $\Phi_1 \vee \Phi_2 \mapsto \text{hpre} : \text{seq.pre} = .\text{or leftPremise.pre rightPremise.pre}$  — the disjunction must be the *whole* premise tree, which is precisely the reach limitation the commentary discusses.
- conclusion post  $\mapsto \text{hpost} : \text{seq.post} = \text{leftPremise.post}$ ; the judgment  $\mapsto$  the goal  $\text{seq.semanticallyValid H}$ .

Width note, deliberate and one-sided: the certified statement set also carries the context-carrying satellite (`OrECtxStep`, `sound_orECtx`, `cx_not_derivable`, `orECtx_not_elaborable`). Those statements are *about the generalization*, not the displayed rule: `sound_orECtx` is strictly wider (a conjunct path addresses a disjunction *inside* the premise tree; the displayed rule is its identity-path case), and the two negative statements certify that the extension is proper — its instance is underivable in, and not elaborable into, the plain core. The displayed rule itself corresponds to `sound_orE` with no width gap in either direction.

## Lean verifier receipts

module BernsteinLogic.Soundness; bound build a20d90e66c13... (bound from receipt a9c0e34d3e3c9c8c, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

```

## HOL verifier receipts

**documentary** Documentary citations. Spine census: bern\_joins GREEN under hol-strict (55 theorems, 0 offences, 208-theory ancestry including this theory), checkJoins\_eq\_checkPf verified verbatim in the built signature. The cited famEq lemma is the kernel-checked per-node equivalence: under well-formed columns (wfColumns/mkCtx/nodeCorr) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations

are documentary. Semantic stratum, also ported: the soundness twins `sound_orE` (theory `bern_tr_soundstruct`: `hol-strict` clean, 9 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources) and `sound_orEctx` (theory `bern_tr_kitd`, 9 theorems, 0 offences, same run — the context from the wire's tag carries), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named `future work`.

## Proof

Genre: core rule (tier 1). Setting as in the `Ax` section; counterexamples read over the one-wire hypernet. This section also carries the fork note on the rule's *reach*: the plain form quoted here, its mechanized limitation, and the context-carrying generalization of which it is the boundary case.

**Claim (`sound_orE`).** The payload supplies two branch sequents  $\Phi_1 \vdash \Psi$  and  $\Phi_2 \vdash \Psi$  with their sub-derivations and three tree identities: the branches share one conclusion (`postMatch`), the conclusion's premise is the disjunction  $\Phi_1 \vee \Phi_2$  of the branch premises (`preEq`), and the conclusion's post is the left branch's post (`postEq`). If both branch sequents are semantically valid, so is  $\Phi_1 \vee \Phi_2 \vdash \Psi$ .

**Theorem R7.1** (soundness of  $\vee E$ , plain form). *Under the three payload identities, semantic validity of both branch sequents implies semantic validity of the conclusion, over every hypernet.*

*Proof.* Let  $\sigma$  be admissible with  $\sigma$  satisfying the conclusion's premise, which `preEq` pins as the tree  $\Phi_1 \vee \Phi_2$ .

*Step 1 (case split).* The  $\vee$ -clause of satisfaction is meta-disjunction:  $\sigma \models \Phi_1$  or  $\sigma \models \Phi_2$ .

*Step 2 (either branch delivers).* In the first case, left branch validity gives  $\sigma \models \Psi$  directly (`postEq`). In the second, right branch validity gives satisfaction of the right branch's conclusion, which `postMatch` identifies — as a tree — with the left's, hence with the conclusion's post.  $\square$

**Remark R7.2** (`postMatch` is load-bearing). The branches must agree on what they conclude *before* the split is trusted. Drop `postMatch` and take the left branch  $w \leq 0 \vdash w \leq 0$  and the right branch  $\top \vdash \top$  (both `Ax` instances): the degenerate rule, reading its conclusion from the left branch, concludes  $(w \leq 0) \vee \top \vdash w \leq 0$  — false at  $\sigma(w) = 1$ , where the premise holds through the right disjunct. `preEq`'s removal admits the context-swap family (the `WEAKEN` section); `postEq`'s removal frees the conclusion outright. In the lattice reading the rule is the bounding half of join's universal property —  $x \leq z$  and  $y \leq z$  iff  $x \sqcup y \leq z$  — whose introducing half is  $\vee I$ .

**Remark R7.3** (the reach problem, and why it is a theorem). `preEq` demands that the eliminated disjunction *be* the whole premise. But in this calculus the disjunctions worth eliminating almost never are: a sequent's premise in practice has the shape  $\Gamma \wedge SP$  — a context conjoined with the synthesized case facts of the hypernet's primitives (a cell indicator's finite case list, a rectifier's sign split) — so the disjunction arrives as a *conjunct* of the premise, one or more  $\wedge$ -nodes deep. The plain rule cannot reach it, and the core cannot restructure its way there, because distributing  $\wedge$  over  $\vee$  is underivable there. That is a theorem, not a design suspicion. Interpret formulas into  $M_3$ , the five-element diamond — three pairwise-incomparable atoms between  $\perp$  and  $\top$ , the canonical modular non-distributive lattice [21] — in full:  $\wedge$  to meet,  $\vee$  to join,  $\top$  to top,  $\perp$  to bottom, three disequality atoms on designated wires to the three lattice atoms, region atoms to bottom, and every remaining atom to top. Work over a hypernet all of whose wires are untyped; that hypothesis is what discharges every non-structural rule (typing packs force closed terms there, region and arithmetic payloads are handled by their conclusion shapes or turn absurd, and the payload-free rules are vacuous). Then a derivable sequent's premise always interprets  $\leq$  its conclusion — by induction on derivations, one case per rule, the structural cases being precisely the lattice axioms of order, meet, and join: the sections `Ax` through  `$\vee E$`  in this book, one kit lemma each (`ProofObject.m3sound`). No rule of the *plain core* — the calculus as quoted in these sections, prior to the context-carrying extension of **Remark R7.4**, whose whole point is otherwise — consumes distributivity. Now take the distribution instance  $P \wedge (Q \vee R) \vdash (P \wedge Q) \vee (P \wedge R)$ : its premise interprets to  $a \sqcap (b \sqcup c) = a \sqcap \top = a$ , its conclusion to  $(a \sqcap b) \sqcup (a \sqcap c) = \perp \sqcup \perp = \perp$ , and  $a \not\leq \perp$  — so no core derivation concludes it (`cx_not_derivable`), even though both branch premises  $P \wedge Q \vdash \cdot$  and  $P \wedge R \vdash \cdot$  are two-step core derivations (an `Ax` node and a  $\vee I$  node each).

**Remark R7.4** (the context-carrying form, and the fork discipline). The repair is not restructuring but a stronger elimination. The context-carrying rule's payload adds a *conjunct path*  $\pi$  into the premise's  $\wedge$ -tree, with read and replace obligations: the conjunct at  $\pi$  is a disjunction  $\Phi_1 \vee \Phi_2$ , each branch premise is the conclusion's premise with that conjunct replaced by the respective disjunct, and both branches conclude the common conclusion (`orEctxStep`). Three mechanized facts locate it precisely. *Sound*: whenever both branch premises are semantically valid, so is the conclusion, over every hypernet (`sound_orEctx` — one path-read lemma to extract the disjunction, the case split of Theorem R7.1, one path-replace lemma to transport each branch's strengthened premise). *Proper*: no elaboration of the context-carrying rule into the core exists (`orEctx_not_elaborable`) — concretely, at the conjunct path addressing  $Q \vee R$  as the premise's right conjunct, the read obligation returns that disjunction and the replace obligations return the branch premises  $P \wedge Q$  and  $P \wedge R$  of **Remark R7.3**'s instance (`cxStep`); its branches are derivable there and its conclusion is not, so the extension proves something true that the core cannot reach. *Conservative at the boundary*: at  $\pi =$  here the rule elaborates into the plain constructor (`orEctxStep.elabHere`) — the form proven sound above is exactly the identity-path case. The cost side of the fork is small and bounded: the certificate carries the path, the checker two small path functions (`read-at`, `replace-at`), and the soundness proof one lemma about conjunct-path replacement. The alternative — adding  $\wedge$ -restructuring rules to the core (rules whose premise and conclusion rearrange the same conjuncts: reassociations, permutations) — cannot substitute: such rules are sound for every lattice interpretation, so the induction above absorbs them — as it absorbs any rule that preserves

$M_3$ -order — and the countermodel stands; closing the gap requires a rule whose soundness genuinely uses distributivity, which is the context-carrying elimination itself. The accompanying development accordingly treats the context-carrying form as the intended elimination rule; the constructor quoted in this section’s Lean cell is the plain form, destined to become its boundary alias.

| proof step                                     | formal anchor                                                                        |

| Remark R7.4: boundary elaboration              | OrECtxStep.elabHere                                                                  |

## Rule 8. EQELIM (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *EqElim*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash t = u \quad \Phi \vdash \Psi[a := t] \quad \exists s. \text{bshape}_H(t) = s = \text{bshape}_H(u)}{\Phi \vdash \Psi[a := u]} \text{EQELIM}$$

EQELIM is Leibniz substitution as a proof rule: an established equality  $t = u$  licenses replacing  $t$  by  $u$  at a designated hole in an established formula. The payload names the hole (a wire  $a$ ), the body formula  $\Psi$ , and the two terms; premises prove  $t = u$  and  $\Psi[a := t]$  over the shared context, and the conclusion is  $\Psi[a := u]$ . A producer reaches for it wherever a derived fact must be rewritten along an equality: pushing a resolved value through a bound (the ReLU rules conclude equalities such as  $y = h$  exactly so that this rule can consume them), transporting an atom across a NORM-derived respelling, or assembling transitivity — which is not primitive in this calculus: a one-node derivation through this rule (the proof section's closing remark spells it out; EQREFL and EQSYM complete the kit).

What the checker recomputes: both substitution instances — it applies the (binder-free, hence capture-free) substitution function to  $(\Psi, a, t)$  and to  $(\Psi, a, u)$  and demands syntactic equality with the cited premise and conclusion formulas — plus the premise-sharing equations, and the typing side condition:  $t$  and  $u$  carry a *common defined* broadcast shape in the ambient hypernet. Nothing semantic is consulted; every side condition is a decidable syntactic equation.

The typing condition is the load-bearing hypothesis. Equality atoms hold *elementwise under broadcast*, so a scalar can stand equal to a vector whose every entry it matches — a genuine, derivable, usable fact that is nonetheless not a license to interchange the two terms: in a region atom, which constrains the shape of its term, the substitution flips satisfiability. Dropping the condition admits a concrete derivation of an unsatisfiable conclusion from a satisfiable premise (the proof section constructs it); with the condition, that certificate is refused because no common shape exists. Dropping either substitution equation instead would let the conclusion be an arbitrary formula; dropping the premise-match would combine facts proven under different contexts.

notes Producer-side, equational obligations are typically discharged by congruence-closure engines [188, 189]; the certificate carries not the closure computation but its residue — a chain of EQREFL/EQSYM/EQELIM nodes, each checked by recomputing one substitution.

  (hconclSubU : substituteInFormula bodyForm wire termU seq.post) :
  seq.semanticallyValid H

```

**The substitution the rule trusts, in full.** The payload fields `bodySubT` and `conclSubU` are equations against the substitution function displayed below: plain leaf replacement over a grammar with no binders, so no capture or freshness side condition exists anywhere. A skeptical reader should confirm by eye that `substituteInFormula` is nothing but that equation — the rule manipulates formulas syntactically and consults no valuation; semantic truth enters only through `sound_eqElim`, from the premise validity hypotheses.

## Correspondence (Steele display ↔ Lean)

reviewer-certified against the displayed texts

The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display

conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in **Ax**; sub-derivation premises as at **WEAKEN**.

- $t, u \mapsto \text{termT} \text{ termU} : \text{Term}$ ; the hole  $a \mapsto \text{wire} : \text{Wire}$ ; the body  $\Psi \mapsto \text{bodyForm} : \text{Formula}$ ;  $\Phi \mapsto \text{seq.pre}$ , shared with both premise sequents through **hpre** and **hpreMatch**.
- the equality premise  $\Phi \vdash t = u \mapsto \text{ihEq}$  with the shape tie **heqPost** : **eqPremise.post** = **.atom .eq termT termU**.
- the body premise  $\Phi \vdash \Psi[a := t] \mapsto \text{ihBody} : \text{bodyPremise.semanticallyValid H}$ , its post tied to  $\Psi[a := t]$  by **hbodySubT**; the goal post is tied to  $\Psi[a := u]$  by **hconclSubU**. Both ties run through **substituteInFormula**, quoted in full below: the one-line equation  $F' = F.\text{subst } w \text{ } t$  over plain leaf replacement — the grammar has no binders, so no capture or freshness side condition exists to omit.
- the typing premise  $\exists s. \text{bshape}_H(t) = s = \text{bshape}_H(u) \mapsto \text{htyEq}$ : existence of one shape  $s$  with **termT.bshape H = some s** and **termU.bshape H = some s** — the **some** carries the definedness the display's equation chain asserts by letting  $s$  range over shapes.
- conclusion  $\Phi \vdash \Psi[a := u] \mapsto$  the goal **seq.semanticallyValid H**. Certified alongside as the semantic engine: **Term.evalQ\_subst\_congr** and **Formula.holds\_subst\_congr** — substitution congruence along equal evaluations, the two lemmas the soundness proof routes through.

No width difference in either direction: statement and display carry the same typing gate (the commentary's counterexample is what its absence admits), and every hypothesis is consumed.

## Lean verifier receipts

module **BernsteinLogic.Soundness**; bound build **a20d90e66c13...** (bound from receipt **a9c0e34d3e3c9c8c**, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

## HOL verifier receipts

**documentary** hol-strict CLEAN census over the ported checker theory: `bern_catalogue`, 472 theorems, 0 cheat-tagged, 0 nonstandard axioms (whitelist: `DISK_THM`; the four `bool` axioms) — verification run of 2026-07-22 on an isolated build host, against a content-addressed checkout of the exact sources cited here — the earlier stale-run caveat (a 2026-07-18 script revision postdating the prior census) is retired by this run, which attests the current text. There is no signed HOL receipt store yet — these citations are documentary. Scope note, honest: the substitution core of this rule's check is what is ported; the broadcast-shape side condition (`tyEq`) rides the hypernet typing island, which the port deliberately defers to its proof-object stage. Semantic stratum, also ported: the soundness twin `sound_eqElim` (theory `bern_tr_fragclose`: `hol-strict clean`, 26 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

## Proof

Genre: core rule (tier 1) — an ordinary mathematical proof at Putnam-exam-solution detail. Every hypothesis of the rule is used below and remarked on; the formal-anchor table maps each step to the Lean declaration that carries it. This section also fixes the semantic setting that the other equality and conversion sections cite.

**Setting.** Fix a hypernet  $H$ . A *valuation*  $\sigma$  assigns each *typed* wire a tensor of its declared shape over its declared dtype (an extended dtype admits infinite entries; untyped wires are assigned nothing), and  $\sigma$  is *admissible* when every primitive application in  $H$  satisfies its semantic relation — as at the `Ax` setting. The rational term evaluation  $\text{ev}_\sigma(t)$  is *partial* and the evaluator is structural and *strict* — a compound term evaluates exactly when its parts evaluate and the constructor's own side condition is met: shapes joining for the binary operations, nothing further for negation, a rank-1 operand with in-range index for projection — so a mention of an untyped wire, a wire holding an infinite value of an extended dtype, a broadcast-incompatible operation, or a projection whose operand is not rank-1 or whose index is out of range yields no value. A comparison atom  $t_1 \bowtie t_2$  *holds* at  $\sigma$  when both sides evaluate and the evaluated tensors stand in the relation  $\bowtie$  *elementwise under broadcast*: equal shapes compare entry by entry; a rank-0 (scalar) tensor against a tensor of any shape compares against every entry; two unequal positive-rank shapes never compare. A region atom holds when its term evaluates to a rank-1 tensor of extent the region's ambient dimension whose entries form a rational point of the region — a rank-0 evaluation is never coerced to a one-dimensional point. A sequent  $\Phi \vdash \Psi$  is *semantically valid* when every admissible  $\sigma$  satisfying  $\Phi$  satisfies  $\Psi$ ; counterexamples in the equality and conversion sections read, as at the `Ax` setting, over application-free hypernets, where every valuation is admissible, so an unsound conclusion genuinely falsifies. Note two consequences that drive everything below: equality atoms are *evaluation-level* facts, not syntactic ones; and a holding equality

between tensors of *different* broadcast shapes (a scalar against a vector) does not make the two sides interchangeable — it only says the scalar matches every entry.

**Claim** (sound\_eqElim). The rule’s payload supplies a hole wire  $a$ , terms  $t, u$ , a body formula  $\Psi$ , and checked side conditions: the two premises share the composite premise  $\Phi$ ; the first premise concludes the atom  $t = u$ ; the second premise concludes  $\Psi[a := t]$ ; the conclusion is  $\Psi[a := u]$ ; and (the typing condition)  $\exists s. \text{bshape}_H(t) = s = \text{bshape}_H(u)$  — both terms carry a *common defined* broadcast shape in  $H$ . If both premises are semantically valid, so is  $\Phi \vdash \Psi[a := u]$ .

**Lemma R8.1** (substitution congruence, term level). *Fix  $\sigma$ , and suppose  $\text{ev}_\sigma(t) = \text{ev}_\sigma(u)$  as partial values (both undefined, or both defined and equal). Then for every term  $e$ ,  $\text{ev}_\sigma(e[a := t]) = \text{ev}_\sigma(e[a := u])$ .*

*Proof.* Structural induction on  $e$ . The base case  $e = a$  is the hypothesis; the base cases  $e$  a constant or a different wire are reflexivity; every compound constructor is a congruence of the evaluator (the evaluator of a sum, product, difference, negation, or projection is a function of the evaluations of the parts). Two remarks. First, the hypothesis and conclusion are equalities of *partial* values — the lemma never manufactures definedness, it only transports whatever is there; in the theorem, definedness will come out of the equality premise. Second, the term grammar has no binders, so substitution is plain leaf replacement and no capture condition is needed anywhere.  $\square$

**Lemma R8.2** (substitution congruence, formula level). *Under the hypothesis of Lemma R8.1: for every formula  $F$ ,  $\sigma \models F[a := t]$  iff  $\sigma \models F[a := u]$ .*

*Proof.* Induction on  $F$ . Comparison atoms substitute in both sides and satisfy the same relation by Lemma R8.1; a region atom substitutes in its term slot only (its simplex and extension-set data carry no wires), so its holding — an assertion about the evaluated tensor — transports the same way;  $\wedge$  and  $\vee$  are the inductive steps;  $\top$  and  $\perp$  are untouched by substitution.  $\square$

**Lemma R8.3** (the shape pin). *Suppose  $\sigma \models t = u$ , and suppose  $t$  and  $u$  carry a common defined broadcast shape  $s$  in  $H$ . Then  $\text{ev}_\sigma(t) = \text{ev}_\sigma(u)$  — equality of tensors, not merely the elementwise relation.*

*Proof.* The holding atom yields evaluations  $A$  of  $t$  and  $B$  of  $u$  in the elementwise-equality relation. Broadcast-shape soundness (Term.evalQ\_bshape) pins  $A.\text{shape} = s = B.\text{shape}$ : a defined evaluation of a bshape-typed term lands exactly at the declared broadcast shape. Elementwise equality at *equal* shapes is equality of the (equal-length) entry lists, position by position, hence equality of the tensors. This is the one step that consumes the typing condition, and it is false without it: the elementwise relation between a rank-0 tensor and a vector says only that the scalar matches every entry (Remark R8.5).  $\square$

**Theorem R8.4** (soundness of EQELIM). *Under the payload’s checked hypotheses, if  $\Phi \vdash t = u$  and  $\Phi \vdash \Psi[a := t]$  are semantically valid, then so is  $\Phi \vdash \Psi[a := u]$ .*

*Proof.* Fix an admissible  $\sigma$  with  $\sigma \models \Phi$ . By validity of the first premise,  $\sigma \models t = u$ ; with the typing condition, Lemma R8.3 upgrades this to  $\text{ev}_\sigma(t) = \text{ev}_\sigma(u)$  (both defined and equal, so in particular equal as partial values). By validity of the second premise — its premise formula is  $\Phi$  itself, by the checked premise match —  $\sigma \models \Psi[a := t]$ . Lemma R8.2 transports this to  $\sigma \models \Psi[a := u]$ , which is the conclusion formula by the checked substitution equation.  $\square$

**Remark R8.5** (why the typing condition is not decoration). Drop the common-shape condition and the rule is *unsound* (orientation of the equality atom flipped here to spare an EQSYM step). Let  $v$  be a wire of shape  $[1]$  over  $\mathbb{Q}$ , let  $\Delta$  be the segment  $\text{conv}(1, 2) \subset \mathbb{Q}^1$ , and take

$$\Phi := (v = \frac{3}{2}) \wedge (v \in \mathcal{R}(\Delta, \emptyset)).$$

$\Phi$  is satisfiable: set  $v := [3/2]$ ; the equality holds by rank-0 broadcast (the scalar  $3/2$  matches the single entry), and the region atom holds.  $\text{Ax}$  and  $\wedge\text{E}$  derive  $\Phi \vdash v = 3/2$  and  $\Phi \vdash v \in \mathcal{R}(\Delta, \emptyset)$ ; the un-gated rule with body  $\Psi := (a \in \mathcal{R}(\Delta, \emptyset)), t := v, u := 3/2$  then concludes  $\Phi \vdash (\frac{3}{2} : \text{Term}) \in \mathcal{R}(\Delta, \emptyset)$  — which is *unsatisfiable*: a constant term evaluates to a rank-0 tensor, and a region atom demands a rank-1 tensor of extent equal to the ambient dimension. A satisfiable premise, an unsatisfiable conclusion. The root cause is precisely the gap between “elementwise equal under broadcast” and “interchangeable”:  $3/2 = [3/2]$  holds without the terms being exchangeable in region contexts. With the typing condition the payload is uninhabitable here —  $\text{bshape}_H(\frac{3}{2}) = []$  while  $\text{bshape}_H(v) = [1]$ , and no common  $s$  exists — so the certificate refuses. Note what the repair does *not* do: broadcast equalities remain derivable and usable as facts; what is forbidden is exactly using one as a Leibniz license.

**Remark R8.6** (the equational kit; relation to practice). EQELIM with EQREFL and EQSYM (next two sections) completes a certificate-side equational kit: reflexivity and symmetry are primitive, and transitivity is a one-node derivation — from  $\Phi \vdash t = u$  and  $\Phi \vdash u = w$ , apply EQELIM with body  $\Psi := (t = a)$ , the hole wire  $a$  chosen fresh for  $t$  (substitution replaces *every* occurrence of  $a$ , so a hole occurring in  $t$  would rewrite  $t$  itself), rewriting the  $u$  in the *first* premise (taken as body premise,  $\Psi[a := u]$ ) to  $w$ ; the derived node inherits the common-shape typing obligation on  $(u, w)$  — broadcast equality is not transitive without it (two tensors of unequal positive-rank shapes never compare, yet each can stand equal to one scalar between them:  $[0] = 0$  and  $0 = [0 \ 0]$  both hold while  $[0] = [0 \ 0]$  does not). On the producer side, equational goals are typically discharged by congruence-closure engines [188, 189]; what ships in a certificate is not the closure computation but its residue: a chain of EQREFL/EQSYM/EQELIM nodes, each checked by syntactic recomputation of one substitution.

## Rule 9. EQREFL (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *EqRefl*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\exists s. \text{bshape}_H(t) = s \quad \text{wires}(t) \text{ finitely typed in } H}{\Phi \vdash t = t} \text{EQREFL}$$

EQREFL derives  $\Phi \vdash t = t$ , premise-free, for an arbitrary context  $\Phi$  (a fact true in the empty context is true under any premise; the proof never reads  $\Phi$ ). A producer uses it to seed equalities: the starting point of an EQELIM rewrite chain (transitivity, in particular, derives from these three rules and begins here), and the  $t = t$  obligations that alias unpacks and worked derivations demand.

That the rule has side conditions at all is its content. Equality atoms in this calculus are facts about *evaluation*, and evaluation is partial — a wire of an extended dtype can hold  $\pm\infty$  and fail the rational read; a shape-incompatible sum never evaluates. So “ $t = t$ ” costs something: the checker verifies the two typing conditions the semantics actually needs — the term's broadcast shape is *defined* in the hypernet, and every free wire is typed at a *finite* dtype. Under exactly these, evaluation is total at every valuation and reflexivity is free; drop either and the un-gated rule asserts an invalid sequent under the empty premise — in one case a conclusion failing only at extended-valued assignments, in the other one unsatisfiable outright (the proof section gives one concrete refutation per field). Nothing else is consulted: no premise, no admissibility, no evaluation — both conditions are static typing checks against the hypernet.

**notes** Where NORM applies, EQREFL is its diagonal; it is kept primitive so the equational kit stands in fragments that omit the polynomial engine entirely.

### Lean statement

BernsteinLogic.Soundness . Term.evalQ\_defined\_of\_bshape\_fin

statement bound

```
-- Totality of evaluation under the B13 typing pack: a `bshape`-typed
-- term over finitely-typed wires evaluates. Structural – no polynomial
-- view, so idx projections are covered (their rank-1 + range gates are
-- part of `bshape`). -/
theorem Term.evalQ_defined_of_bshape_fin {H : Hypernet} (σ : H.Valuation) :
  ∀ (t : Term) (s : Shape), t.bshape H = some s → t.finWires H →
  ∃ q, Term.evalQ σ t = some q ∧ q.shape = s
```

BernsteinLogic.Soundness . QTensor.rel2\_refl

statement bound

```
-- Reflexive relations lift to `rel2` on any tensor against itself. -/
theorem QTensor.rel2_refl {r : Q → Q → Prop} (hr : ∀ x, r x x)
  (a : QTensor) : QTensor.rel2 r a a
```

BernsteinLogic.Soundness . sound\_eqRefl

statement bound

```
-- EqRefl: under the B13 typing pack, t evaluates, and elementwise
-- equality against itself holds. -/
theorem sound_eqRefl {H : Hypernet} {seq : Sequent} {t : Term}
  (htyDef : ∃ s, t.bshape H = some s) (hfin : t.finWires H)
  (hpost : seq.post = .atom .eq t t) :
  seq.semanticallyValid H
```

**The two typing predicates, in full.** Both payload fields are static checks against the hypernet's wire typing — no valuation appears. `Term.bshape` is the broadcast-tolerant shape synthesis (scalars join with any shape; the projection case carries its own rank and range gates); `Term.finWires` demands a finite (non-extended) dtype at every free wire.

BernsteinLogic.Core.Catalogue . Term.bshape

definition bound

```
-- Broadcast-tolerant shape of a term: shapes must agree up to rank-0
-- broadcast (a scalar joins with any shape); dtypes are NOT consulted. -/
def Term.bshape (H : Hypernet) : Term → Option Shape
```

```

  (postEq : seq.post = .atom .eq term term)
  : PEqRefldata H seq

```

## Correspondence (Steele display ↔ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in Ax.

- $t \mapsto$  the binder  $t : \text{Term}$ ; the two displayed typing premises  $\mapsto$  `htyDef`: existence of a shape  $s$  with  $t.bshape\ H = \text{some } s$  (defined broadcast shape — the `some` is the definedness), and `hfin` :  $t.finWires\ H$  (every free wire typed at a finite dtype, quoted below). Both are static checks against the hypernet; no valuation appears.
- conclusion  $\Phi \vdash t = t \mapsto$  the goal under `hpost` : `seq.post = .atom .eq t t`; the arbitrary context  $\Phi$  is premise-freeness by silence — no hypothesis mentions `seq.pre`, so the statement holds under every premise (the same representation the `PConstExact` dictionary describes).
- certified alongside as the semantic engine: `Term.evalQ_defined_of_bshape_fin` — under exactly the two typing conditions, evaluation is total at every valuation, at the synthesized shape — and `QTensor.rel2_refl`, the reflexivity of the elementwise comparison lifting.

No width difference in either direction: both typing hypotheses are consumed, and the proof section refutes the rule with either one dropped.

## Lean verifier receipts

module BernsteinLogic.Soundness; bound build a20d90e66c13... (bound from receipt a9c0e34d3e3c9c8c, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust

the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

## HOL verifier receipts

documentary Documentary citations. Family validation: bern\_fam\_resid built GREEN with all ten famEq arms validated, hol-strict clean; spine census: bern\_joins GREEN under hol-strict (55 theorems, 0 offences, 208-theory ancestry including this theory), checkJoins\_eq\_checkPf verified verbatim in the built signature. The cited famEq lemma is the kernel-checked per-node equivalence: under well-formed columns (wfColumns/mkCtx/nodeCorr) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twin sound\_eqRefl (theory bern\_tr\_ready8: hol-strict clean, 8 theorems, 0 offences,

verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (checkPf\_sound\_frag, theory bern\_tr\_splice, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of hol-strict runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

## Proof

Genre: core rule (tier 1). Setting (valuations, partial evaluation, elementwise-under-broadcast atom semantics) as fixed in the EQELIM section.

**Claim** (sound\_eqRef1). The payload supplies a term  $t$  and two checked typing conditions:  $\text{bshape}_H(t)$  is *defined* (some shape  $s$ ), and every free wire of  $t$  is typed at a *finite* (non-extended) dtype. Then  $\Phi \vdash t = t$  is semantically valid for an *arbitrary* premise  $\Phi$  — the rule is premise-free, and  $\Phi$  rides along unread (a fact true in the empty context is true under any premise). Indeed the proof below never reads  $\Phi$ , the admissibility of  $\sigma$ , or the premise-satisfaction hypothesis at all: the conclusion holds at *every* valuation.

That anything must be checked here at all is the point of the section. Equality atoms are evaluation-level facts (EQELIM setting), so “ $t = t$ ” is not free: it asserts that  $t$  *evaluates* — and evaluation is partial.

**Lemma R9.1** (totality under the typing pack). *If  $\text{bshape}_H(t) = s$  and every free wire of  $t$  is finitely typed, then at every valuation  $\sigma$  the evaluation  $\text{ev}_\sigma(t)$  is defined, with shape  $s$ .*

*Proof.* Structural induction on  $t$ ; both typing conditions descend to subterms (a subterm’s free wires are among  $t$ ’s, and  $\text{bshape}$  is synthesized bottom-up, so a defined  $\text{bshape}$  for  $t$  is defined on every subterm). A wire read succeeds because the wire is typed at a finite dtype — an untyped wire declares no dtype at all, so the finite-wires condition already excludes it: the valuation’s entries lie in the dtype’s value set, which for a finite dtype contains no  $\pm\infty$ , so the whole-tensor rational read succeeds, at the declared shape. A constant evaluates to its rank-0 tensor. For a compound term, the induction hypotheses give defined operands whose shapes are, by the definition of  $\text{bshape}$  (quoted in full beside this section), either equal or joinable through rank-0 broadcast — and on such shapes the elementwise operations are total; the result lands at the join. A projection’s rank-1-and-in-range gates are part of  $\text{bshape}$ ’s definedness, so the projected read is in range. (Term.evalQ\_defined\_of\_bshape\_fin.)  $\square$

**Lemma R9.2** (reflexivity lifts). *For any tensor  $A$ , the elementwise-under-broadcast equality relation holds between  $A$  and  $A$ .*

*Proof.* The shapes are equal, so the relation reads the entry list zipped against itself: every pair on the diagonal is  $(x, x)$ . (QTensor.rel2\_refl.)  $\square$

**Theorem R9.3** (soundness of EQREFL). *Under the payload’s typing conditions,  $\Phi \vdash t = t$  is semantically valid for every  $\Phi$ .*

*Proof.* Fix  $\sigma$ . Lemma R9.1 gives  $\text{ev}_\sigma(t) = A$  for some tensor  $A$ ; Lemma R9.2 closes the atom with both sides read as  $A$ .  $\square$

**Remark R9.4** (why each typing condition is load-bearing). Drop the finite-wires condition: let  $w$  be a wire of an *extended* dtype (its value set admits  $+\infty$ ), and let  $\sigma$  assign it a tensor with an infinite entry — admissible, since nothing constrains a bare wire. The rational read of  $w$  fails,  $t := w$  does not evaluate, and the atom  $w = w$  is *false* at  $\sigma$ ; with  $\Phi := \top$  the sequent  $\top \vdash w = w$  is refuted. Drop shape-definedness: take  $t := w_1 + w_2$  with  $w_1$  of shape [2] and  $w_2$  of shape [3], both finite — every wire reads, but the elementwise sum refuses the incompatible shapes,  $t$  never evaluates, and  $\vdash t = t$  is again *false* everywhere. In both cases the un-gated rule would assert an invalid sequent under a satisfiable (indeed empty) premise — in the first case the conclusion fails at the exhibited valuation (a finite assignment would satisfy it); in the second it is unsatisfiable outright. The typing pack is exactly the semantic price of equality-by-evaluation; it is the same field family that repairs NORM, there compounded with canonical-form equality.

**Remark R9.5** (taxonomy note). Wherever NORM applies, EQREFL is its diagonal ( $t_1 = t_2 = t$ , canonical forms trivially equal). It is nonetheless kept primitive: the development’s frozen minimal fragment (v0 in the sources) excludes the polynomial engine outright, and the equational kit must stand without it.

## Rule 10. EQSYM (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *EqSym*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash t = u}{\Phi \vdash u = t} \text{EQSYM}$$

EQSYM flips an equality atom: from  $\Phi \vdash t = u$  conclude  $\Phi \vdash u = t$ . The need is real because downstream consumers of equalities match atoms *syntactically* with a fixed orientation — EQELIM's equality premise, in particular, names its two terms in order — while only the combination rules expose both polarities of an equality in their own matching. A producer whose congruence engine emits  $t = u$  but whose rewrite needs  $u = t$  inserts this one node.

What the checker recomputes: three syntactic form equations (premise atom, conclusion atom, shared context) — nothing else. The rule carries *no* typing fields, and that absence is principled twice over: the premise's holding atom already witnesses both evaluations (nothing must be manufactured, contrast EQREFL), and the elementwise-under-broadcast equality relation is symmetric branch by branch, so no shape agreement is needed (contrast EQELIM, whose typing condition guards transport into a *different* formula — exactly what a flip never does).

Every payload field is structural; there is no droppable hypothesis to exhibit a counterexample against. The rule is core rather than admissible because its would-be unpack (through EQREFL + EQELIM) demands typing side data the premise atom does not syntactically carry — the unpack is not computable from the node it would replace.

### Lean statement

  (postEq     : seq.post = .atom .eq termU termT)
  : PEqSymData H seq
```

### Correspondence (Steele display ↔ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display

conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in **Ax**; sub-derivation premise as at **WEAKEN**.

- $t, u \mapsto \text{tT } \text{tU} : \text{Term}$ ; the premise judgment  $\Phi \vdash t = u \mapsto \text{ih}$  with the shape tie  $\text{hpremPost} : \text{premise.post} = .\text{atom} .\text{eq } \text{tT } \text{tU}$ ;  $\Phi \mapsto \text{premise.pre}$ , shared via  $\text{hpre}$ .
- conclusion  $\Phi \vdash u = t \mapsto$  the goal under  $\text{hpost} : \text{seq.post} = .\text{atom} .\text{eq } \text{tU } \text{tT}$  — the same two term binders, transposed; nothing else changes.
- certified alongside: `QTensor.re12_symm`, the branchwise symmetry of the elementwise comparison lifting — the reason no typing field exists (the premise's holding atom already witnesses both evaluations, as the commentary explains).

No width difference in either direction; every hypothesis is consumed.

**HOL verifier receipts**

[documentary](#) Documentary citations. Family validation: `bern_fam_resid` built GREEN with all ten `famEq` arms validated, `hol-strict clean`; spine census: `bern_joins` GREEN under `hol-strict` (55 theorems, 0 offences, 208-theory ancestry including this theory), `checkJoins_eq_checkPf` verified verbatim in the built signature. The cited `famEq` lemma is the kernel-checked per-node equivalence: under well-formed columns (`wfColumns/mkCtx/nodeCorr`) at this rule's wire tag, the columnar family check coincides with the flat reference walk's arm for this rule. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twin `sound_eqSym` (theory `bern_tr_b14`: `hol-strict clean`, 2 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

**Proof**

Genre: core rule (tier 1). Setting as fixed in the `EqELIM` section.

**Claim** (`sound_eqSym`). The payload supplies terms  $t, u$ ; the premise concludes the atom  $t = u$  over premise formula  $\Phi$ , shared with the conclusion sequent; the conclusion is the atom  $u = t$ . If the premise is semantically valid, so is  $\Phi \vdash u = t$ .

**Lemma R10.1** (the elementwise relation of a symmetric relation is symmetric). *Let  $r$  be a symmetric binary relation on  $\mathbb{Q}$ , and suppose tensors  $A, B$  stand in the elementwise-under-broadcast lift of  $r$ . Then  $B, A$  stand in it too.*

*Proof.* The lift has three live branches, and each is separately symmetric — this per-branch analysis is the entire content, so we spell it out. *Equal shapes*: the relation reads the zipped entry lists; the swapped claim reads the zip in the other order, and each swapped pair is closed by symmetry of  $r$ . *Rank-0  $A$  against positive-rank  $B$* : the hypothesis says  $r(A_{\text{scalar}}, y)$  for every entry  $y$  of  $B$ ; the swapped claim is judged in the *other* scalar-broadcast branch (rank-0 on the right), which demands  $r(y, A_{\text{scalar}})$  for every  $y$  — symmetry of  $r$ , pointwise. *Rank-0  $B$* : mirror image. Two unequal positive-rank shapes never stand in the lift, so there is nothing to prove there. (`qTensor.rel2_symm`)  $\square$

**Theorem R10.2** (soundness of `EqSYM`). *If  $\Phi \vdash t = u$  is semantically valid, so is  $\Phi \vdash u = t$ .*

*Proof.* Fix an admissible  $\sigma \models \Phi$ . The premise yields evaluations  $A$  of  $t$  and  $B$  of  $u$  in the elementwise equality lift. Present the same two evaluations in the opposite roles:  $u$  evaluates to  $B$ ,  $t$  to  $A$ , and Lemma R10.1 (with  $r$  the symmetric relation  $=$ ) closes the atom  $u = t$ .  $\square$

**Remark R10.3** (the negative space: what this rule does *not* need). The rule has no droppable side condition — every payload field is structural (the three form equations) — so the honest remarks here concern the two fields conspicuously absent. No typing pack (`EqREFL`'s `tyDef/fin`): the premise's holding atom already *witnesses* both evaluations, and symmetry only re-uses the premise's own evidence; nothing must be manufactured. No common-shape condition (`EqELIM`'s `tyEq`): Lemma R10.1 is shape-agnostic — a broadcast equality flips to the mirror broadcast equality, same content, no interchangeability claim ever made. The contrast triangulates `EqELIM`'s repair: the typing condition there guards *transport into a different formula*, which is exactly what `EqSYM` never does.

**Remark R10.4** (why a primitive, when a two-node unpack exists on paper). From  $\Phi \vdash t = u$  one can derive  $\Phi \vdash u = t$  through `EqREFL` + `EqELIM`: body  $\Psi := (a = t)$  with the hole wire  $a$  fresh for  $t$  — substitution replaces *every* occurrence of  $a$ , and freshness is what makes  $\Psi[a := t]$  the atom  $t = t$  and  $\Psi[a := u]$  the atom  $u = t$  — rewriting the left occurrence of  $t$  in  $t = t$  to  $u$ . But the

derivation demands EQREFL’s typing pack on  $t$  and EQELIM’s common-shape condition on  $(t, u)$  — side data the premise atom does not syntactically carry, and which a producer cannot always reconstruct at the flip site. The primitive constructor instead consumes the premise’s semantic evidence directly (the proof above), making the flip unconditional. In the catalogue’s three-tier taxonomy that obstruction is what sorts EQSYM core rather than admissible: the unpack is not payload-computable from the node it would replace.

| proof step                                     | formal anchor                                                                                                                                   |

## Rule 11. ANTISYM (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *Antisym*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash t \leq u \quad \Phi \vdash t \geq u}{\Phi \vdash t = u} \text{ ANTISYM}$$

ANTISYM squeezes an equality out of two opposite bounds: from  $\Phi \vdash t \leq u$  and  $\Phi \vdash t \geq u$  — the same two terms, the same context — conclude  $\Phi \vdash t = u$ . A producer reaches for it wherever a pinching argument closes: an optimization pass that certifies matching upper and lower bounds on the same quantity, a fixed-point equality assembled from two directional inequalities, or any pipeline whose native outputs are order facts but whose consumer (EQELIM's rewrite chains, in particular) wants an equality atom.

The rule earns its place in the core by a non-derivability fact, not by convenience: equality-from-inequalities has no derivation in the remainder of the calculus. Provably — an induction over derivations shows that every equality concluded from an equality-atom-free context equates terms with identical polynomial normal forms — so no chain of existing rules can ever conclude  $t = u$  from the two bounds when the sides are genuinely different terms. Historically the calculus carried this inference only inside two bespoke rules for the ReLU function, which were thereby load-bearing for something much more general than ReLU; with antisymmetry available as its own rule, that monopoly ends.

The side conditions are purely structural: two premise-atom form equations, the conclusion-atom form equation, and the two context equations tying each premise sequent to the conclusion's context. No typing fields — and the absence is principled (contrast EQREFL, which must *manufacture* an evaluation and so carries the typing pack): each premise atom holds only where both sides already evaluate finitely at compatible shapes, and that is exactly the evaluation evidence the equality atom's semantics consumes. Dropping either premise leaves a one-sided bound, and any strictly-below evaluation pair refutes the un-gated rule.

One reading discipline, stated here because the conclusion invites over-reading: the concluded equality holds in the calculus's elementwise-under-broadcast sense, which suffices for the truth of the atom and for every consumer that reads it semantically — but it is not a license to interchange  $t$  and  $u$  inside an arbitrary formula. Substitution rides EQELIM, whose common-defined-shape typing condition remains in force unchanged (that section constructs the refutation its absence would admit).

**notes** This rule is *staged, not enacted*: what exists today is the statement register — the soundness theorem below, proven in Lean with a HOL twin — while the certificate format knows nothing of it yet. No payload constructor, no wire tag, no checker arm: a certificate cannot currently carry an ANTISYM node, and this section will gain its checker-side anchors when enactment lands. The mathematics is settled; the plumbing is queued.

### Lean statement

BernsteinLogic.Soundness . QTensor.rel2\_conj

statement bound

```
/-- Two `rel2` facts at the SAME tensor pair combine pointwise: the
broadcast branch taken is a function of the two shapes alone, so the
quantified domains coincide and the pointwise conjunction lifts.
(Stated for `sound_antisym`; any pointwise combination rides it.) -/
theorem QTensor.rel2_conj {r s t : Q → Q → Prop}
  (hrst : ∀ x y, r x y → s x y → t x y) {a b : QTensor}
  (hr : QTensor.rel2 r a b) (hs : QTensor.rel2 s a b) :
  QTensor.rel2 t a b
```

BernsteinLogic.Soundness . sound\_antisym

statement bound

```
/-- Antisym: `≤` and `≥` premise validities at the same term pair force
the equality atom — entrywise `le_antisymm` lifted through `rel2`
(`QTensor.rel2_conj`: both premises constrain the same evaluated pair,
so the broadcast branches align). Like `sound_eqSym` and unlike
`sound_eqRefl`, no B13 typing pack is needed: the premise atoms only
hold where both sides already evaluate finitely, which is exactly the
evaluation evidence the conclusion atom needs. Core rather than
derived: the equality-from-inequalities inference has no catalogue
derivation — provably, since derivable equalities from eq-free contexts
have canonically-equal sides — so the rule must be primitive
(ReLU-Pos/Neg had been core solely as carriers of this inference). -/
```

```
theorem sound_antisym {H : Hypernet} {seq premiseLe premiseGe : Sequent}
  {tT tU : Term}
  (ihLe : premiseLe.semanticallyValid H)
  (ihGe : premiseGe.semanticallyValid H)

## Correspondence (Steele display $\leftrightarrow$ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in Ax; sub-derivation premises as at **WEAKEN**.

- $t, u \mapsto tT \ tU : \text{Term}$ ; the two premise judgments  $\Phi \vdash t \leq u$  and  $\Phi \vdash t \geq u \mapsto ihLe, ihGe$  with the shape ties  $hpreLePost : \text{premiseLe.post} = .\text{atom} .\text{le} \ tT \ tU$  and  $hpreGePost : \text{premiseGe.post} = .\text{atom} .\text{ge} \ tT \ tU$  — note the  $\geq$  premise binds its own atom former at the *same* binder order ( $tT, tU$ ), not a flipped  $\leq$  atom.
- the shared context: the display writes one  $\Phi$  across all three sequents; the statement renders it as *two* equations,  $hpreLe : \text{seq.pre} = \text{premiseLe.pre}$  and  $hpreGe : \text{seq.pre} = \text{premiseGe.pre}$  — each premise tied to the conclusion's context, premise-to-premise equality following by transitivity. Same content, one equation more than the display suggests.
- conclusion  $\Phi \vdash t = u \mapsto$  the goal under  $hpost : \text{seq.post} = .\text{atom} .\text{eq} \ tT \ tU$ .
- no typing hypotheses appear on either side — principled, as the commentary explains (the premise atoms carry the evaluation evidence; contrast **EQREFL**'s `htyDef/hfin`).
- certified alongside as the semantic engine: **QTensor.reI2\_conj** — two elementwise-under-broadcast facts at the *same* tensor pair combine pointwise, because the broadcast branch taken is a function of the two shapes alone, so the quantified domains coincide. The soundness proof feeds it entrywise antisymmetry of the rational order.

Width note, both directions: every hypothesis is consumed, and the one place statement and display could be read apart is the conclusion atom's broadcast-sense semantics — the proven equality is the elementwise-under-broadcast lift (a scalar can stand equal to a vector whose every entry it matches), which is the equality atom's meaning everywhere in this calculus; the commentary's reading discipline names what that does *not* license.

## Lean verifier receipts

module BernsteinLogic.Soundness; bound build a20d90e66c13... (bound from receipt a9c0e34d3e3c9c8c, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

| receipt          | minted               | layers             | status  |
|------------------|----------------------|--------------------|---------|
| a9c0e34d3e3c9c8c | 2026-08-03T21:30:36Z | build+decorrelated | current |

21 further receipt(s) in the store attest superseded builds of this module and are omitted from this rendering.

gate-layer coverage of the bound build:

build (lake build (elaboration)) **current**

replay (leanchecker (official kernel replay)) **stale only**

hardened (safe\_verify (hardened screen)) **stale only**

decorrelated (lean4export + nanoda (decorrelated kernel)) **current**

**comparator: none** no fixture in the three-implementation comparator harness (compiled / kernel-interpreted / reference-interpreted) exercises this rule.

## HOL4 statement

theory bern\_tr\_antisym, HOL4 development script bern\_tr\_antisymScript.sml script bound**Theorem qtRel2\_conj**

```

## HOL verifier receipts

documentary Documentary citations, one register-honest caveat: this theory is the staged rule's whole standalone footprint (both theorems in one theory, deliberately, so the staged work moves as a unit), and — unlike the enacted siblings on this page — no isolated-build-host verification census is attached to it yet; the citation attests the script text, not a checked build artifact. Statement fidelity follows the ported-soundness register used throughout: the Lean statement's implicit arguments become leading universals and its curried named hypotheses a conjunction in source order; `.atom .le/.ge/.eq` renders as `FAtom BowLe/BowGe/BowEq`; the pointwise antisymmetry witness closes by the rational order's antisymmetry lemma. Because the rule has no checker arm, there is no family-check or certified-fragment claim to make here — the semantic stratum is the entire port, matching the statement-register staging the note describes.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

## Proof

Genre: core rule (tier 1), staged — statement register only; see the section note. Setting as fixed in the EQELIM section.

**Claim** (`sound_antisym`). Two premise sequents conclude the atoms  $t \leq u$  and  $t \geq u$ , each over the premise formula  $\Phi$  shared with the conclusion sequent; the conclusion is the atom  $t = u$ . If both premises are semantically valid, so is  $\Phi \vdash t = u$ .

**Lemma R11.1** (elementwise lifts at a shared tensor pair combine pointwise). *Let  $r, s, w$  be binary relations on  $\mathbb{Q}$  with  $r(x, y) \wedge s(x, y) \Rightarrow w(x, y)$  for all  $x, y$ , and suppose tensors  $A, B$  stand in the elementwise-under-broadcast lift of  $r$  and also in the lift of  $s$ . Then they stand in the lift of  $w$ .*

*Proof.* The branch the lift takes is a function of the two shapes alone — not of the relation — so the two hypotheses and the goal all quantify over the *same* domain, and the pointwise implication closes each point. Spelled per branch: *equal shapes*: all three statements read the same zipped entry lists, pair by pair. *Rank-0 A against positive-rank B*: all three quantify  $A$ 's scalar against each entry of  $B$ ; mirror image for rank-0  $B$ . *Two unequal positive-rank shapes*: no lift holds there at all, so the hypothesis for  $r$  is already false and there is nothing to prove. (`QTensor.reL2_conj`.) □

**Theorem R11.2** (soundness of `ANTISYM`). *If  $\Phi \vdash t \leq u$  and  $\Phi \vdash t \geq u$  are semantically valid, so is  $\Phi \vdash t = u$ .*

*Proof.* Fix an admissible  $\sigma \models \Phi$ . The  $\leq$  premise yields evaluations  $A$  of  $t$  and  $B$  of  $u$  in the elementwise  $\leq$ -lift; the  $\geq$  premise yields evaluations  $A'$  of  $t$  and  $B'$  of  $u$  in the elementwise  $\geq$ -lift. Evaluation is a function of the valuation and the term, so  $A' = A$  and  $B' = B$ : both premises constrain the *same* evaluated pair, which is what makes Lemma R11.1 applicable at all. Apply it with  $r := \leq$ ,  $s := \geq$ ,  $w := =$  and the pointwise fact  $x \leq y \wedge x \geq y \Rightarrow x = y$  — antisymmetry of the order on  $\mathbb{Q}$  — and the equality lift closes the atom  $t = u$ . □

**Remark R11.3** (the negative space: no typing pack, and why both premises). No typing fields (`EQREFL`'s `tyDef/fin`): that rule must *manufacture* an evaluation for its premise-free conclusion, and pays for totality with static typing conditions; here each premise atom holds only where both sides already evaluate finitely at compatible shapes, and the proof above consumes exactly that evidence — nothing is manufactured (`EQSYM` makes the same economy for the same reason). Both orientations are load-bearing: dropping either premise leaves a one-sided bound, and any evaluation pair with  $A$  strictly below  $B$  entrywise satisfies the surviving premise while refuting the conclusion — the counterexample is immediate at scalar shape already.

*Remark R11.4* (what the broadcast-sense conclusion does not license). The concluded atom holds in the elementwise-under-broadcast sense: a scalar stands equal to a vector whose every entry it matches. That is the equality atom’s meaning everywhere in this calculus — sufficient for atom truth and for every consumer that reads the atom semantically — but it is not a license to interchange  $t$  and  $u$  inside an arbitrary formula. Substitution rides EQELIM, whose common-defined-shape typing condition remains in force unchanged: that section constructs a satisfiable-to-unsatisfiable flip from exactly the scalar-equals-vector equalities this rule can legitimately conclude.

*Remark R11.5* (why core, and what is staged). Core because the inference is not derivable: an induction over derivations shows every equality concluded from an equality-atom-free context equates terms with identical polynomial normal forms, so no chain of existing rules concludes  $t = u$  from the two bounds when the sides are genuinely different terms. Historically the calculus carried antisymmetry only inside two bespoke rules for the ReLU function; a core ANTISYM ends that monopoly and lets bespoke rules be judged on their own content. Staged: the theorem above is the statement register — no payload constructor, wire tag, or checker arm exists yet, so certificates cannot carry the rule today; the anchors table below will gain its “wired as core” line at enactment.

| proof step    | formal anchor                                                                              |
|---------------|--------------------------------------------------------------------------------------------|
| Lemma R11.1   | QTensor.rel2_conj                                                                          |
| Theorem R11.2 | sound_antisym; statement register only — not yet wired (no ProofObject constructor exists) |
| HOL twin      | theory bern_tr_antisym: qtRel2_conj, sound_antisym                                         |

## Rule 12. CONVELIM (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *ConvElim*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash x \in \mathcal{R}(\Delta, S)}{\Phi \vdash \bigwedge_{i=0}^n \text{canon}(\epsilon_i \lambda_i(x)) \leq 0 \quad \epsilon_i = +1 \text{ if } i \in S, \quad -1 \text{ if } i \in \bar{S}} \text{CONVELIM}$$

CONVELIM opens a region atom: from  $\Phi \vdash x \in \mathcal{R}(\Delta, S)$  it concludes the region's defining barycentric halfspace conjunction — one  $(\cdot) \leq 0$  atom per support vertex, in a pinned canonical spelling. It is the entry move of every argument that reasons *linearly* about a geometric premise: BERNCON consumes region atoms natively, but the combination rules (FARKAS, SYZGY) match ordinary comparison atoms by exact canonical polynomial, and this rule is what turns a region fact into atoms they can see.

What the checker recomputes: the *entire* conclusion, from  $(x, \Delta, S)$  alone — the two barycentric affine forms of the 1-D two-vertex support (weights are determined on a simplex, so nothing is chosen and nothing rides the certificate), the sign-folding that turns each core vertex's wanted  $\lambda \geq 0$  into a  $(-\lambda) \leq 0$  atom (the all- $\leq$  discipline the downstream matchers consume), and the strictly positive primitive-integer rescale that makes the spelling unique — then demands syntactic equality with the cited conclusion. No producer text is trusted; the side condition is one decidable equation. Outside the checkable fragment (ambient dimension 1, support exactly two vertices at distinct coordinates) the build refuses and the rule cannot fire — refusal is trivially sound, and the distinct-coordinates gate is precisely where a degenerate simplex's division by zero is made unrepresentable.

The rule needs no typing or positivity fields: definedness and shape of the region term are read out of the region atom's own semantics. Dropping the premise-form equation would sever the conclusion from any premise at all; dropping the canonical-spelling pin would not make the rule unsound but would strand its conclusions — equivalent spellings never match downstream — which is why the spelling is checked rather than suggested.

notes Geometric reading of extension sets, 1-D:  $S = \emptyset$  is the segment  $[V_0, V_1]$ ; naming one vertex stretches the region to the closed ray away from the other — membership with a *nonpositive* weight on the extended vertex. The region atom is thus the calculus's interface between simplex geometry and sign arithmetic, and this rule with CONVLNTR is that interface's two directions, exact inverses on the fragment.

### Lean statement

BernsteinLogic.Soundness . barycentricHalfspaceBuild\_spec

statement bound

```
/-- Structure of a successful barycentric-halfspace build (the 1-D case
`baryCoeffs1D` gates): the F4 all- $\leq$  canonical conjunction, one
`f4VertexAtom` per vertex of the filter pair. -/
theorem barycentricHalfspaceBuild_spec {t : Term} {simplex : Simplex}

## Correspondence (Steele display ↔ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in **AX**; sub-derivation premise as at **WEAKEN**.

- $x \mapsto \text{term} : \text{Term}; \Delta \mapsto \text{simplex} : \text{Simplex}; S \mapsto S : \text{ExtensionSet}$ ; the premise judgment  $\Phi \vdash x \in \mathcal{R}(\Delta, S) \mapsto \text{ih}$  with the shape tie  $\text{hpremiseForm} : \text{premise.post} = \text{.inRegion term simplex S}; \Phi$  shared via  $\text{hpre}$ .

- the *entire* displayed conclusion — the flat conjunction, its vertex order, the sign pattern  $\epsilon_i$ , the affine spellings  $\lambda_i$  —  $\mapsto$  one hypothesis, `hhalf : barycentricHalfspaceForm term simplex S seq.post`: `seq.post` is literally the value of the verified canonical build. The display's  $\lambda_i$  and  $\epsilon_i$  are not statement binders but *outputs* of `barycentricHalfspaceBuild`, quoted in full below.
- conclusion judgment  $\mapsto$  the goal `seq.semanticallyValid H`; certified alongside, `barycentricHalfspaceBuild_spec` unpacks a successful build run into the geometric data the soundness proof consumes.

Width note, narrower and loud about it: a successful build run forces ambient dimension 1 with support exactly two vertices at distinct coordinates (the first conjuncts of `barycentricHalfspaceBuild_spec`), so the mechanized statement covers exactly the one-dimensional instance of the displayed general-dimension rule. Outside that fragment the build returns `none`, the hypothesis is unsatisfiable, and the rule cannot fire — refusal, never unverified acceptance; the displayed rule at higher dimension is design intent, not yet certified statement.

Spelling alignment, formerly a live discrepancy: the displayed conclusion and the certified build now agree — both state the flat sign-folded  $\text{all-}\leq$  conjunction, each atom  $\text{canon}(\epsilon_i \lambda_i(x)) \leq 0$  with the extension/core orientation carried by the sign  $\epsilon_i$  (`f4VertexAtom` negates the core vertex's affine form into the term and compares  $\leq 0$  — the commentary describes this discipline). Earlier printings displayed a mixed  $\leq/\geq$  per-vertex comparator pattern; the roster cell has since been reconciled to the realized form, and this certification binds the reconciled texts.

## Lean verifier receipts

module `BernsteinLogic.Soundness`; bound build `a20d90e66c13...` (bound from receipt `a9c0e34d3e3c9c8c`, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

| receipt                       | minted               | layers             | status  |

**HOL verifier receipts**

**documentary** hol-strict CLEAN census over the ported checker theory: bern\_catalogue, 472 theorems, 0 cheat-tagged, 0 nonstandard axioms (whitelist: DISK\_THM; the four bool axioms) — verification run of 2026-07-22 on an isolated build host, against a content-addressed checkout of the exact sources cited here. The earlier loud caveat (the canonical-form revision of 2026-07-18 postdated the prior census run) is retired: this run attests exactly the quoted text. There is no signed HOL receipt store yet, and these citations are documentary. Semantic stratum, also ported: the soundness twin sound\_convElim (theory bern\_tr\_fragclose: hol-strict clean, 26 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (checkPf\_sound\_frag, theory bern\_tr\_splice, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of hol-strict runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

## Proof

Genre: core rule (tier 1). Setting (valuations, partial evaluation, elementwise atom semantics) as fixed in the EQELIM section; this section additionally fixes the region-atom semantics and the canonical halfspace form, which the CONVINTRO section then cites.

**Region atoms, in the checkable fragment.** A region atom  $x \in \mathcal{R}(\Delta, S)$  holds at  $\sigma$  when the extension set  $S$  is tied to the simplex  $\Delta$ , the region term evaluates to a rank-1 tensor of extent equal to the ambient dimension, and the point it holds lies in the *masked region*: it is an affine combination of  $\Delta$ 's vertices with weights summing to 1, nonnegative on core vertices and *nonpositive* on the vertices named by  $S$ . The rules below operate in the fragment their checker accepts — ambient dimension 1, support exactly two vertices  $a, b$  at distinct coordinates  $V_0 \neq V_1$  — where the geometry is completely explicit: the two barycentric weights are *determined*, affine in the point,

$$\lambda_a(x) = \frac{V_1 - x}{V_1 - V_0}, \quad \lambda_b(x) = \frac{x - V_0}{V_1 - V_0}, \quad \lambda_a + \lambda_b \equiv 1,$$

and the region is: the segment  $[V_0, V_1]$  for  $S = \emptyset$ ; the closed ray from  $V_1$  away from  $V_0$  for  $S = \{a\}$  (weight of the extended vertex  $\leq 0$ ); the mirror ray for  $S = \{b\}$ . ( $S$  is a proper subset, so both-extended does not arise.) Determinacy of the weights is why elimination below is complete — no witness is chosen, none rides the certificate.

**The canonical halfspace form.** The conclusion is not “some conjunction equivalent to the sign facts” but one *pinned* formula, recomputed by the checker from  $(x, \Delta, S)$  alone: one atom per support vertex, in support order, each in  $(\cdot) \leq 0$  shape: for  $v \in S$  the atom  $\text{canon}(\lambda_v(x)) \leq 0$ , for  $v \notin S$  the atom  $\text{canon}(-\lambda_v(x)) \leq 0$  (the wanted  $\lambda_v \geq 0$  *sign-folded* into the term — the all- $\leq$  discipline), where  $\text{canon}$  rescales the affine pair (slope, offset) by a *strictly positive* rational to its primitive-integer representative and lays the atom body out in degree-sorted shape. If the build's gates fail (dimension  $\neq 1$ , support  $\neq 2$  vertices,  $V_0 = V_1$ , or the atom's simplex not the cited  $\Delta$ ), the build refuses, the payload is uninhabitable, and the rule cannot fire: refusal is trivially sound, and in the degenerate-simplex case it is also where a division by zero would otherwise live — made unrepresentable rather than checked-then-divided.

**Claim** (sound\_convElim). If  $\Phi \vdash x \in \mathcal{R}(\Delta, S)$  is semantically valid and the conclusion formula is the canonical halfspace form for  $(x, \Delta, S)$ , then  $\Phi \vdash$  (that conjunction) is semantically valid.

**Lemma R12.1** (structure of a successful build). *If the canonical build succeeds with output  $F$ , then the ambient dimension is 1,  $S$  is tied to  $\Delta$ , the support filter returns exactly  $[a, b]$  with constant vertex coordinates  $V_0 \neq V_1$ , and  $F$  is the conjunction of the two vertex atoms described above.*

*Proof.* Unfold the build: each claim is one of its gates, and the output shape is its final assembly. (barycentricHalfspaceBuild\_spec.)  $\square$

**Lemma R12.2** (canonical atom  $\leftrightarrow$  raw sign fact). *Let  $q$  be a defined, singleton-shaped evaluation of  $x$  at  $\sigma$ , and let  $(\text{off}, \text{slp})$  be an affine pair. The vertex atom for membership flag  $m$  holds at  $\sigma$  iff*

$$m = \text{true} : \quad \text{off} + \text{slp} \cdot q \leq 0, \quad m = \text{false} : \quad 0 \leq \text{off} + \text{slp} \cdot q.$$

*Proof.* Two steps. *Sign-folding*: for  $m = \text{false}$  the build negates the pair before canonicalizing, so the emitted atom asserts  $\text{canon}(-\lambda) \leq 0$ , i.e. the displayed  $\geq$ . *The rescale is sign-transparent*:  $\text{canon}$  multiplies the pair by  $k > 0$  — in the generic case  $k = L/g$  with  $L$  a positive lcm of denominators and  $g$  a positive gcd of the scaled numerators; in the zero-offset case the output slope is the sign  $\text{sgn}(\text{slp})$ , i.e. the pair scaled by  $1/|\text{slp}|$  — well-defined on every pair in play: a successful barycentric build has distinct vertices, so each emitted affine pair carries slope  $\pm 1/(V_1 - V_0) \neq 0$  (sign-folding only negates it), and in the zero-offset case that slope is the whole pair; for the degenerate all-zero pair, which no successful build emits, both sides of the displayed equivalence hold trivially and the statement is unaffected — and a strictly positive rescale of an affine function has the same sign locus. The atom's left side evaluates (constants and one already-defined  $q$ ), at singleton shape, so the elementwise reading is the scalar comparison of the displayed value against 0. (f4VertexAtom\_holds\_iff; the rescale is primAffine, the layout f4Lhs.)  $\square$

**Lemma R12.3** (region elimination, two-vertex case). *Suppose  $\sigma \models x \in \mathcal{R}(\Delta, S)$  in the fragment of Lemma R12.1, with  $q$  the evaluated coordinate. Then, conditionally on membership: if  $a \in S$  then  $\lambda_a(q) \leq 0$ , if  $a \notin S$  then  $\lambda_a(q) \geq 0$ ; likewise for  $b$ .*

*Proof.* The masked-region witness consists of weights on the support summing to 1 that reproduce  $q$  and satisfy the sign discipline. On a two-vertex support the reproduction and sum equations force the weights to be exactly  $\lambda_a(q), \lambda_b(q)$  (two linear equations, invertible since  $V_0 \neq V_1$ ), so the witness's sign discipline is the displayed conditional facts. (maskRegion\_pair\_elim.)  $\square$

**Theorem R12.4** (soundness of `CONVELIM`). *Under the payload’s checked hypotheses, if  $\Phi \vdash x \in \mathcal{R}(\Delta, S)$  is semantically valid, so is  $\Phi \vdash F$  for the built conclusion  $F$ .*

*Proof.* Fix an admissible  $\sigma \models \Phi$ . Premise validity gives the region atom at  $\sigma$ : in particular  $x$  *evaluates*, to a rank-1 extent-1 tensor (the atom’s own shape field — no typing pack is needed here; contrast [Remark R12.6](#)), whose scalar is  $q$ . Lemma [R12.3](#) delivers the four conditional sign facts; Lemma [R12.2](#) converts, per vertex, the applicable one into the built vertex atom; Lemma [R12.1](#) says the conclusion is exactly the conjunction of those two atoms.  $\square$

*Remark R12.5* (why a pinned canonical spelling). The combination rules downstream (`FARKAS`, `SYZGY`) match premise atoms *by exact canonical polynomial*; a conclusion emitted in any equivalent-but-different spelling would simply never match, stranding the geometric fact. Pinning the spelling in the checker — which recomputes the build from  $(x, \Delta, S)$  and demands syntactic equality with the cited conclusion, trusting no producer text — makes the emitted atoms the *same* tokens every producer and every downstream matcher agrees on. The all- $\leq$  polarity keeps each atom in the  $(\cdot) \leq 0$  normal form those rules consume, and the positive primitive-integer rescale makes the representative unique. Note the checked object is the *formula*, not a semantic condition: this rule’s side condition is one syntactic equation, decidable by construction.

*Remark R12.6* (what is *not* hypothesized). No shape or finiteness fields appear in this payload: elimination reads definedness and shape out of the region atom itself. The mirror rule cannot — its premise is the halfspace conjunction, whose atoms tolerate broadcast and are satisfied by a *scalar*  $x$  — and that asymmetry is exactly where `CONVINTRO`’s one extra typing field comes from (next section).

| proof step                                                                   | formal anchor                                                                                                                                                                                   |

## Rule 13. CONVINTRO (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *ConvIntro*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash \bigwedge_{i=0}^n \text{canon}(\epsilon_i \lambda_i(x)) \leq 0 \quad \epsilon_i = +1 \text{ if } i \in S, -1 \text{ if } i \in \bar{S} \quad \text{bshape}_H(x) = [n]}{\Phi \vdash x \in \mathcal{R}(\Delta, S)} \text{ CONVINTRO}$$

CONVINTRO closes a region atom: from the canonical barycentric halfspace conjunction for  $(x, \Delta, S)$  — the same pinned formula CONVELIM emits, recomputed by the same build — it concludes  $\Phi \vdash x \in \mathcal{R}(\Delta, S)$ . A producer uses it to re-enter the geometric world after arithmetic: a subdivision branch or a combination argument establishes the two vertex atoms, and this rule converts them back into the region fact that BERNCONC or a further region rule consumes.

What the checker recomputes: the build (as in CONVELIM — one syntactic equation, producer text untrusted, refusal outside the 1-D two-vertex fragment), plus this rule's one extra typing field:  $\text{bshape}_H(x) = [d]$ , the region term is statically rank-1 of the ambient extent. The asymmetry with CONVELIM is principled: elimination reads the term's shape out of the region atom it consumes, while introduction is handed only halfspace atoms — which hold *elementwise under broadcast* and are perfectly satisfied by a scalar  $x$  — so the shape must arrive as a checked hypothesis. Drop it and a closed scalar inside the segment yields a satisfiable (indeed universally true) premise whose region conclusion is unsatisfiable — a rank-0 tensor never satisfies a region atom; the proof section builds the refutation concretely. It is the same broadcast liberality that breaks un-gated EQELIM, repaired by the same typing-field pattern.

**notes** On the fragment, CONVINTRO and CONVELIM are exact inverses — membership, the four weight-sign facts, and the canonical conjunction are three presentations of one determinate-weight geometry, so the pair is a lossless interface between region atoms and the arithmetic fragment.

### Lean statement

BernsteinLogic.Soundness . Term.evalQ\_bshape

statement bound

```

## Correspondence (Steele display $\leftrightarrow$ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in `AX`; sub-derivation premise as at `WEAKEN`; binders as at `CONVELIM`, mirrored.

- the displayed premise conjunction  $\mapsto$  `hhalf : barycentricHalfspaceForm term simplex S premise.post` — the same verified build, its value now equated with the *premise's* post; the premise judgment  $\mapsto$  `ih`, context shared via `hpre`.
- the display's typing premise  $\text{bshape}_H(x) = [n] \mapsto \text{htermShape} : \text{term.bshape } H = \text{some } [\text{simplex.complex.ambDim}]$  — statically rank-1 at the ambient extent, the one hypothesis `CONVELIM` does not have; the commentary derives why introduction needs it and elimination does not.
- conclusion  $\Phi \vdash x \in \mathcal{R}(\Delta, S) \mapsto$  the goal under `hpost : seq.post = .inRegion term simplex S`.

Width note: the same one-dimensional fragment confinement as `CONVELIM`, forced by the same spec conjuncts — the mechanized statement is the displayed rule at ambient dimension 1; outside it the build refuses and nothing is accepted unverified. The `CONVELIM` dictionary's spelling alignment carries over unchanged: the displayed premise conjunction and the certified premise formula both state the build's sign-folded  $\text{all-}\leq$  shape, the extension/core orientation carried by the sign  $\epsilon_i$  — same halfspaces, same folded spelling, display and mechanization reconciled.

## Lean verifier receipts

module BernsteinLogic.Soundness; bound build a20d90e66c13... (bound from receipt a9c0e34d3e3c9c8c, 2026-08-03T21:30:36Z). A receipt records that named checking layers accepted a build: (module, compiled-artifact SHA-256, environment SHA-256, checker layers), minted when the checking gate ran; the store receipts attesting the bound build are listed with the layers each run credited. Nothing here asks the reader to trust the store: every layer is an independently runnable program over the quoted sources — rebuild the module and re-run the checkers to reproduce the verdict. Receipts attesting superseded builds credit no layer and are omitted from this rendering (the count of omissions, if any, is noted below).

## HOL verifier receipts

documentary hol-strict CLEAN census over the ported checker theory: bern\_catalogue, 472 theorems, 0 cheat-tagged, 0 nonstandard axioms (whitelist: DISK\_THM; the four bool axioms) — verification run of 2026-07-22 on an isolated build host, against a content-addressed checkout of the exact sources cited here — the re-attestation the CONVELIM cell's earlier caveat awaited (the canonical-form revision of 2026-07-18 postdated the prior census) is this run (documentary citations — no signed HOL

store yet). Scope note: the shape side condition (`termShape`) rides the un-ported hypernet typing island, deferred to the port's proof-object stage. Semantic stratum, also ported: the soundness twin `sound_convIntro` (theory `bern_tr_fragclose`: `hol-strict` clean, 26 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splce`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of `hol-strict` runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named `future work`.

## Proof

Genre: core rule (tier 1). Setting, region-atom semantics, the checkable fragment, and the canonical halfspace form as fixed in the `CONVELIM` section.

**Claim** (`sound_convIntro`). The payload supplies the region data  $(x, \Delta, S)$  and two checked conditions: the premise concludes the canonical halfspace form for  $(x, \Delta, S)$ , and (the shape condition)  $\text{bshape}_H(x) = [d]$  where  $d$  is the ambient dimension — the region term is statically a rank-1 tensor of the ambient extent. If the premise is semantically valid, then  $\Phi \vdash x \in \mathcal{R}(\Delta, S)$  is semantically valid.

**Lemma R13.1** (evaluation recovered from the premise). *Suppose  $\sigma$  satisfies the built conjunction. Then  $x$  evaluates at  $\sigma$ .*

*Proof.* The first vertex atom holds, so its left side — the canonicalized affine image of  $x$ , built from constants and  $x$  by product and sum — evaluates; evaluation of a compound is defined only if evaluation of every part is — the evaluator is strict, each node's value built from its children's values, so a defined parent forces defined children — and inverting it at the product node (and sum node, when the offset is present) yields a value for  $x$  itself. (`f4VertexAtom_holds_inv`)  $\square$

**Lemma R13.2** (shape pinned by the payload field). *With the shape condition, the evaluation of Lemma R13.1 is a rank-1 tensor of extent 1 (the fragment has  $d = 1$ ), hence singleton-shaped, with scalar  $q$ .*

*Proof.* Broadcast-shape soundness: a defined evaluation of a `bshape`-typed term lands at the declared shape (`Term.evalQ_bshape`), here  $[1]$  by the build's dimension gate (`CONVELIM`, Lemma R12.1).  $\square$

**Theorem R13.3** (soundness of `CONVINTRO`). *Under the payload's checked hypotheses, if  $\Phi \vdash F$  is semantically valid for the built conjunction  $F$ , so is  $\Phi \vdash x \in \mathcal{R}(\Delta, S)$ .*

*Proof.* Fix an admissible  $\sigma \models \Phi$ ; premise validity gives both vertex atoms at  $\sigma$ . Lemmas R13.1 and R13.2 produce the singleton evaluation  $q$  of  $x$ . Reading each held atom through the canonical-atom characterization (`CONVELIM`, Lemma R12.2) yields the four conditional sign facts on  $\lambda_a(q)$ ,  $\lambda_b(q)$ . The two-vertex introduction assembles the masked-region witness from exactly these: the weights  $\lambda_a(q)$ ,  $\lambda_b(q)$  sum to 1 and reproduce  $q$  by construction (affine identities, valid since  $V_0 \neq V_1$ ), and the sign discipline — nonnegative on core vertices, nonpositive on  $S$ -vertices — is the four facts (`maskRegion_pair_intro`). Together with the build's tie of  $S$  to  $\Delta$  and the shape of Lemma R13.2, this is the region atom's holding, term slot included.  $\square$

**Remark R13.4** (why the shape condition is not decoration). Drop it and the rule is *unsound*. Over  $\Delta = \text{conv}(1, 2)$ ,  $S = \emptyset$ , instantiate the region term at the *closed scalar*  $t := 3/2$ . The built premise is then a conjunction of two closed atoms asserting  $\lambda_a(3/2) \geq 0$  and  $\lambda_b(3/2) \geq 0$  — both true ( $\lambda_a = \lambda_b = 1/2$ ), so the conjunction holds at *every* valuation, and taking  $\Phi$  to be that very conjunction,  $\text{Ax}$  proves the premise. The un-gated introduction would conclude  $\Phi \vdash (\frac{3}{2} : \text{Term}) \in \mathcal{R}(\Delta, \emptyset)$  — unsatisfiable: a constant evaluates to a rank-0 tensor, and the region atom demands rank 1. Satisfiable premise, unsatisfiable conclusion. The mechanism is the same broadcast liberality that broke the un-gated `EQELIM`: the halfspace atoms constrain the *values* of the affine images and are perfectly happy with a scalar  $x$ ; only the region atom cares about the tensor's shape. The shape field restores, at the introduction rule, the well-formedness that region atoms carry in the source calculus's typing discipline — one repair family (the `EQELIM/NORM` typing pattern), one failure family.

**Remark R13.5** (elimination and introduction are exact inverses on the fragment). On singleton-shaped, well-shaped region terms, Lemmas R12.3 (elimination) and the introduction step above are mutually inverse readings of the same determinate-weight geometry: membership  $\leftrightarrow$  the four sign facts  $\leftrightarrow$  the canonical conjunction. The round trip loses nothing — which is why the pair can serve as the sole interface between region atoms and the arithmetic fragment, with no completeness caveat inside the checkable fragment.

## Rule 14. ARITHATOM (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *ArithAtom*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\Phi \vdash (t_1 - t_2) \bowtie 0}{\Phi \vdash t_1 \bowtie t_2} \text{ARITHATOM}$$

$$\frac{\Phi \vdash t_1 \bowtie t_2}{\Phi \vdash (t_1 - t_2) \bowtie 0} \text{ARITHATOM}^{-1}$$

with  $\bowtie \in \{<, \leq, =, \geq, >\}$ .

ARITHATOM toggles a comparison atom between its two spellings: the *direct form*  $t_1 \bowtie t_2$  and the *zero-normal form*  $(t_1 - t_2) \bowtie 0$ , in both directions (one payload constructor each), for  $\bowtie \in \{<, \leq, =, \geq, >\}$ . It is the adapter at the calculus's normal-form boundary: the combination rules (FARKAS, SYZGY) and the canonical conclusions of the geometry rules live in  $(\cdot) \leq 0$ -normal shapes, while human-facing specifications, box premises of the relaxation rules, and final theorem statements live in direct forms. A producer folds a zero-form conclusion into the literal bound a downstream rule wants, or unfolds a specification atom so its polynomial content can be matched.

What the checker recomputes: two syntactic form equations — the premise (respectively conclusion) must be *literally* the atom built from the same payload terms with the syntactic difference  $t_1 - t_2$  against the literal constant 0 — plus the comparator gate  $\bowtie \neq \neq$  and the shared-context equation. Deliberately severe: no term evaluating to zero, no algebraic rearrangement qualifies (a producer wanting those routes through NORM first); the severity is what keeps the side conditions decidable by construction and the trusted surface at the two form equations, with the comparator gate and the context equation beside them.

There is no droppable typing hypothesis, and that is the rule's quiet achievement: both forms mention the same wires, and whenever either form holds, both evaluations exist and transport — in the fold direction the difference's definedness arrives with the premise, and in the unfold direction it is manufactured from the fact that a *holding* elementwise comparison already certifies broadcast compatibility, on exactly which subtraction is total. The comparator gate is the one non-structural field: the rational semantics would accept  $\neq$  (the entrywise bridge is comparator-uniform), and the gate instead pins the source calculus's comparator set and keeps the development's auxiliary three-valued screen uniform across the atom-shape rules (see the proof section's closing remark — the screen itself would survive  $\neq$  here, unlike at the ground-fact rule).

**notes** The transported object is the per-entry rational comparison  $(p - q) \bowtie 0 \iff p \bowtie q$  — translation invariance of the order of  $\mathbb{Q}$  — lifted entrywise through the broadcast discipline by an invertible totality argument. Exact arithmetic end to end: no rounding, no tolerance, in either direction.

### Lean statement

## Correspondence (Steele display ↔ Lean)

**reviewer-certified against the displayed texts** The dictionary below is a reviewer-certified statement of how the mechanized statements above interpret the displayed rule: display metavariable  $\mapsto$  Lean binder, each display hypothesis  $\mapsto$  the premise or side condition carrying it, the display conclusion  $\mapsto$  the goal — with any deliberate difference in width between display and mechanization named outright. Certification is recorded as a hash triple over (the displayed cell, the extracted statement texts, this dictionary's own text); if any of the three changes, this block turns amber until a reviewer re-certifies. The correspondence claim itself remains editorial — reviewer-grade, not machine-checked; its machine-checked successor types each soundness statement against the rule as a structured object, and supersedes this block per rule as it lands.

Judgment frame as in **AX**; sub-derivation premise as at **WEAKEN**.

- the display's two inference lines  $\mapsto$  the lemma pair, mirroring the payload's two constructors: **ARITHATOM** (zero-form premise, direct conclusion)  $\mapsto$  `sound_arithAtom_fold`; **ARITHATOM**<sup>-1</sup>  $\mapsto$  `sound_arithAtom_unfold`.

- $t_1, t_2 \mapsto \text{termL termR} : \text{Term}; \bowtie \mapsto b : \text{BowTie}$ ; the two spellings  $\mapsto$  the form predicates quoted below, each a one-line syntactic equation: `atomicCompareForm` (the atom is literally  $t_1 \bowtie t_2$ ) and `atomicCompareZero` (literally  $(t_1 - t_2) \bowtie 0$ , syntactic difference against the literal constant).
- $\Phi \mapsto$  the shared context via `hpre`; the premise judgment  $\mapsto \text{ih}$ ; the conclusion  $\mapsto$  the goal `seq.semanticallyValid H`. Certified alongside: `QTensor.map2_defined_of_rel2`, the totality bridge with which the unfold direction manufactures the difference's definedness from the holding premise.

Width note, deliberate and load-bearing (the `PConstExact` pattern): the display restricts  $\bowtie \in \{<, \leq, =, \geq, >\}$ , while both lemmas are proven for *all* constructors of `BowTie`, including  $\neq$  — no  $\bowtie \neq$  hypothesis appears in either statement. The exclusion is an admission-layer fact: the payload's `notNE` field refuses  $\neq$  certificates to protect the three-valued screen the commentary describes. The mechanized statements are therefore strictly wider than the displayed rule, and the displayed rule is exactly the admitted fragment of them.

## Lean verifier receipts

module `BernsteinLogic.Soundness`; bound build `a20d90e66c13...` (bound from receipt `a9c0e34d3e3c9c8c`, 2026-08-03T21:30:36Z). ## HOL verifier receipts

**documentary** hol-strict CLEAN census over the ported checker theory: `bern_catalogue`, 472 theorems, 0 cheat-tagged, 0 nonstandard axioms (whitelist: `DISK_THM`; the four bool axioms) — verification run of 2026-07-22 on an isolated build host, against a content-addressed checkout of the exact sources cited here — the earlier stale-run caveat (a 2026-07-18 script revision postdating the prior census) is retired by this run, which attests the current text. There is no signed HOL receipt store yet — these citations are documentary. Semantic stratum, also ported: the soundness twins `sound_arithAtom_fold` (theory `bern_tr_ready8`: hol-strict clean, 8 theorems, 0 offences, verification run of 2026-07-22 on an isolated build host, content-addressed at the same sources) and `sound_arithAtom_unfold` (theory `bern_tr_fragclose`, 26 theorems, 0 offences, same run), consumed by the certified-fragment keystone (`checkPf_sound_frag`, theory `bern_tr_splice`, 20 theorems, 0 offences, same run): a reference-checker accept inside the proven wire fragment yields sequent validity.

HOL receipts are documentary: quoted results of hol-strict runs and census rows from the HOL4 development's build evidence, not minted receipt artefacts. A HOL receipt store (the Lean store's twin) is named future work.

## Proof

Genre: core rule (tier 1). Setting as fixed in the EQELIM section. The rule is a pair: one payload constructor per direction, sharing the comparator gate; both directions are proven, and the two proofs are deliberately *not* mirror images — the asymmetry is the interesting content.

**Claim** (`sound_arithAtom_fold`, `sound_arithAtom_unfold`). The payload supplies terms  $t_1, t_2$  and a comparator  $\bowtie \in \{<, \leq, =, \geq, >\}$  (the gate  $\bowtie \neq \neq$  is a checked field). The two atom spellings in play, both recomputed syntactically by the checker from the same payload terms, are the *direct form*  $t_1 \bowtie t_2$  and the *zero-normal form*  $(t_1 - t_2) \bowtie 0$ , where the subtrahend side is the literal constant 0 and the left side the literal syntactic difference. *Fold*: premise concludes the zero-normal form, conclusion is the direct form. *Unfold*: the converse. In both directions, validity of the premise sequent gives validity of the conclusion sequent, over the shared  $\Phi$ .

**Lemma R14.1** (scalar bridge). *For  $p, q \in \mathbb{Q}$  and  $\bowtie$  any of the five comparators:  $(p - q) \bowtie 0 \iff p \bowtie q$ .*

*Proof.* Add  $q$  to both sides, respectively subtract it — the order of  $\mathbb{Q}$  is translation-invariant. The argument is uniform in  $\bowtie$ ; it would, for that matter, be equally valid for  $\neq$  — the comparator gate is *not* forced at this level (Remark R14.8).  $\square$

**Lemma R14.2** (tensor bridge). *Let  $A, B$  be tensors whose elementwise difference is defined, say  $D$ . Then  $D$  stands in the elementwise lift of  $\bowtie$  against the rank-0 tensor 0 iff  $A, B$  stand in the elementwise lift of  $\bowtie$ .*

*Proof.*  $D$ 's entries are the pointwise differences under the broadcast discipline: at equal shapes, entry  $i$  of  $D$  is  $A_i - B_i$ ; with rank-0  $A$ , entry  $i$  is  $A_{\text{scalar}} - B_i$ ; with rank-0  $B$ ,  $A_i - B_{\text{scalar}}$  — and  $D$  takes the positive-rank operand's shape (the broadcast join). The left side of the claimed equivalence reads every entry of  $D$  against the scalar 0; the right side reads the operands in the corresponding branch of the elementwise lift. In each of the three branches the two readings pair off the same scalar comparisons entry by entry, and Lemma R14.1 closes each pair. (`qTensor.rel2_sub_zero_iff`.)  $\square$

**Lemma R14.3** (definedness, fold direction). *If the zero-normal atom holds at  $\sigma$ , then both  $t_1$  and  $t_2$  evaluate at  $\sigma$ , and their elementwise difference is the evaluation of  $t_1 - t_2$ .*

*Proof.* The holding atom includes a defined evaluation of the syntactic difference; the evaluator is structural and strict (the Setting: a compound evaluates exactly when its parts evaluate and their shapes join), so inverting it at the subtraction node yields defined evaluations of both operands and the elementwise-difference equation. (`Term.evalQ_sub_inv`.)  $\square$

**Lemma R14.4** (definedness, unfold direction). *If the direct atom holds at  $\sigma$ , then the elementwise difference of the two (defined, by the atom's holding) evaluations is itself defined.*

*Proof.* A holding elementwise comparison forces broadcast-compatible shapes — the lift's fourth branch, unequal positive ranks, is empty — and elementwise subtraction is total on exactly the broadcast-compatible pairs. A holding comparison is thereby itself a compatibility certificate. (`qTensor.map2_defined_of_rel2`.)  $\square$

**Theorem R14.5** (soundness of ARITHATOM, both directions). *Over shared  $\Phi$ : validity of  $\Phi \vdash (t_1 - t_2) \bowtie 0$  gives validity of  $\Phi \vdash t_1 \bowtie t_2$ , and conversely.*

*Proof.* Fix an admissible  $\sigma \models \Phi$  in either direction. *Fold*: the premise's zero-normal atom holds; its constant side evaluates to the rank-0 tensor 0; Lemma R14.3 recovers evaluations  $A, B$  of  $t_1, t_2$  with difference  $D$ , and the premise's relation is  $D \bowtie 0$  elementwise; Lemma R14.2 converts it to  $A \bowtie B$  elementwise — the direct atom, on the operands' own evaluations. *Unfold*: the premise's direct atom holds with evaluations  $A, B$ ; Lemma R14.4 manufactures the difference  $D$ ; the evaluator assembles  $\text{ev}_\sigma(t_1 - t_2) = D$  from its operands' evaluations, the constant side is again rank-0 0, and Lemma R14.2, read right to left, closes the zero-normal atom.  $\square$

**Remark R14.6** (the direction asymmetry, and payload minimalism). The fold direction *consumes* definedness of the difference (the premise evaluated it); the unfold direction must *manufacture* it — and can, precisely because a holding comparison certifies broadcast compatibility (Lemma R14.4). The consequence is worth stating plainly: whenever either atom *holds*, both operands' evaluations exist and transport to the other form. That is why this payload carries *no* typing or positivity fields at all — compare EQREFL's typing pack, EQELIM's shape agreement, and the positive-size fields of the combination rules: every one of those exists

to manufacture or protect an evaluation this rule gets handed for free. (Definedness itself is not mirrored form to form: at broadcast-incompatible operand shapes the direct form’s sides still evaluate while the zero-normal difference does not — but there neither atom can hold, each failing in its own way, and holding is all the rule transports; at a compatible zero-size shape the two forms hold together, vacuously.) The “exact rational evaluation transported both directions” is exactly the pair (Lemma R14.1, Lemma R14.2): a translation-invariance fact of ordered  $\mathbb{Q}$ , lifted entrywise through an invertible totality argument.

*Remark R14.7* (the syntactic pins). Both form conditions are single syntactic equations recomputed from the payload — the zero-normal form demands the *literal* constant 0 and the *literal* difference term of the same  $t_1, t_2$ , not any term evaluating to zero or any algebraic rearrangement. A producer wanting  $t_1 \bowtie t_2$  from, say,  $(t_2 - t_1) \cdot (-1) \bowtie 0$  routes through `NORM` first; this rule does arithmetic on *atom shape* only. That severity is what makes the side conditions decidable by construction and keeps the rule’s checked surface at two form equations, the shared-context equation, and one comparator gate.

*Remark R14.8* (why  $\neq$  is excluded). Not for the reason one might guess — and not for its sibling’s reason either. Lemmas R14.1 and R14.2 are comparator-uniform, and the rational semantics of this section would accept  $\neq$  without change. Nor would the development’s auxiliary three-valued screen (the countermodel construction that polices vacuity properties, developed at the  $\vee$ E section) break here: both spellings of a  $\neq$  atom mention the same wires, and the screen’s disequality clause reads only designated-wire membership, so fold and unfold preserve its value — unlike at the premise-free ground-fact rule, where a wire-free  $\neq$  atom’s screen value genuinely breaks the invariant (the `PCONSTEXACT` section). The comparator set  $\{<, \leq, =, \geq, >\}$  is the source calculus’s own set for this rule, and the payload’s gate keeps it checked: the screen’s per-rule argument stays a one-clause conclusion-shape case (the gate vacates its  $\neq$  branch), and the two atom-shape rules stay aligned.  $\neq$  remains in the formula grammar — it is simply not this rule’s business to move it across the zero-normal boundary.

## Rule 15. BERNCONe (core rule)

### The rule (Steele metanotation)

as realized in the mechanized development; source row: `rules.toml` — *BernCone*. The metanotation statement is typeset by hand for notational quality; its mechanized ground truth is the Lean statement below, extracted from the sources at every build of this book and hash-bound. The rule *roster* is machine-checked (every mechanized rule tag round-trips to exactly one catalogue row); the statement *text* is editorial, checked by eye against the extracted Lean beside it.

$$\frac{\begin{array}{l} \Delta = \text{conv}(V_0, \dots, V_n) \subset \mathbb{R}^n \text{ an } n\text{-simplex}; \quad S \subsetneq \{0, 1, \dots, n\} \\ \Phi \vdash x \in \mathcal{R}(\Delta, S) \quad p: \mathbb{R}^n \rightarrow W \text{ polynomial map of degree } d, \text{ with coefficient tensor } (b_\alpha)_{|\alpha|=d} \\ \text{wires}(p) = \emptyset \vee (x = w \wedge \text{wires}(p) \subseteq \{w\}) \quad S \neq \emptyset \Rightarrow P \text{ conic}; \quad S = \emptyset \Rightarrow P \text{ convex suffices} \\ (p \text{ idx-free, with } p \text{ constant } \vee n = 1) \vee (p \text{ projection-indexed, indices } < n, S = \emptyset) \\ \text{for every } j \in \mathbb{N}^S \text{ with } |j| \leq d, \text{ every degree-}d \text{ Bernstein coefficient of } P_j \text{ on } F_S \text{ satisfies } P \end{array}}{\Phi \vdash P(p(x))} \text{ BERNCONe}$$

the disjunctive premise on  $p$  is the checker's scope guard: coefficient checks on coordinate polynomials over ambient dimension  $\neq 1$  are refused rather than attempted outside the proven kernels.

BERNCONe is the calculus's arithmetic-closure primitive: from a *geometric* fact (a wire value lies in a region) it derives an *analytic* one of unbounded degree (a polynomial of that value satisfies a predicate) — where the conversion rules exchange region atoms with their defining affine sign conditions, BERNCONe is the rule that concludes something new. From a proven region membership  $\Phi \vdash x \in \mathcal{R}(\Delta, S)$  and a degree- $d$  polynomial term  $p$ , it concludes  $\Phi \vdash P(p(x))$  for any predicate  $P$  of the accepted grammar, provided every certified Bernstein coefficient of  $p$  over the region satisfies  $P$ . A producer reaches for it wherever a Lyapunov decrease, an invariant bound, or an output enclosure must be established over a whole region rather than at sample points: choose a degree, optionally subdivide (SUBDIVIDE is the completeness partner — enclosures converge under degree elevation and subdivision), and emit the payload.

What the checker recomputes, given the payload (simplex, extension set, degree, polynomial term, predicate): that the extension set is tied to the premise's simplex and the simplex is full-dimensional; that the polynomial term translates into the region's ambient coordinates (two routes: an idx-free single-wire canonical form, or the projection-indexed coordinate form); and then — the heart — *every* forward-difference Bernstein coefficient of the translated polynomial over the region, by exact  $\mathbb{Q}$  arithmetic, testing each against the predicate. No coefficient tensors ride the wire: the certificate names the polynomial and the region, and the checker rebuilds the entire coefficient table itself (the recompute pattern), so a forged table is unrepresentable rather than detected.
